1. Project, Architecture, and Build Configuration

What This Project Actually Does

Arrakis: Harvester Down is an interactive, real-time three-dimensional rescue game. The player pilots an ornithopter above a mathematical desert. A moving spice harvester periodically releases workers while a sandworm pursues it. The player must fly to each group, slow down, descend, hold the rescue control, carry a limited number of workers, and deliver them to a landing pad. A worker merely collected aboard is not yet a scored survivor. The game contains a title screen, timed mission, pause overlay, debrief, retry, escalating later missions, and a best score retained in memory.

The program is not a 3D-model viewer and does not parse OBJ files. Its cubes, cylinders, spheres, aerofoil blades, desert grid, rings, eroded rocks, people, worm body, mouth, and teeth are generated in code. Colored materials and procedural shaders replace image textures for world objects. Sound files are the actual disk-loaded runtime assets. The original screenshots, worm photograph, and proposal in docs/reference/ are human references, not inputs used to draw a frame.

The implementation is C++17 with an OpenGL 3.3 core graphics context. GLFW creates the window, receives events, reports time, and provides driver procedure addresses. GLAD turns those addresses into callable OpenGL functions. GLM supplies vectors, matrices, angle conversion, interpolation, and camera transforms. Miniaudio decodes and spatializes sounds, mixes them, and feeds an operating-system audio device. Python and ReportLab are documentation-generation dependencies; neither is required to play the game.

How to Read the Detailed Explanations

Chapters 2 and 3 explain `src/arrakis.cpp`, including the shader programs embedded inside C++ strings. Chapter 4 explains every mission field, state, helper, update path, and deterministic test in `src/arrakis_game.h` and `tests/arrakis_tests.h`. Chapter 5 explains the HUD, bitmap font, radar, and sandworm mesh/animation code. Chapter 6 explains the audio integration in detail and the retained vendor libraries by functional family. Chapter 7 explains the PDF generation tool itself. The numbered appendices include complete retained code and configuration, including miniaudio's large vendor implementation.

Code-range headings refer to physical source-file line numbers. Their purpose is to make small implementation details locatable, not to turn comments or braces into imaginary features. A range can contain several repeated draw calls or assertions; the explanation accounts for what their individual parameters or conditions do. Blank lines provide visual separation and execute nothing. A comment documents an intention but does not run; when a comment and executable behavior disagree, this explanation prioritizes the behavior. The complete source snapshot, file hashes, and source line counts are supplied in the appendix and `docs/documentation_manifest.json`.

Application code is explained much more finely than the third-party libraries: the latter are grouped by algorithms and API families, with their existing comments and full source retained. A library line listing is a reference, not a claim that every branch in every operating-system backend has been rewritten as a unique prose explanation. This distinction matters because miniaudio alone contains approximately 96,000 lines and many backends that this Windows game never executes. External installed GLFW, GLM, and GLAD headers are not project-authored files and are not bundled by this cleanup.

Repository Organization and Cleanup Decisions

`src/` holds five application source/header files. `src/arrakis.cpp` remains the executable's main translation unit: it introduces shared globals and drawing types, then includes project headers where their dependent names are available. The headers are not independently compiled C++ libraries. In particular, the game header assumes terrain and flight state have already been declared, and the worm header assumes rendering helpers exist. This arrangement is preserved instead of introducing a risky architecture rewrite during folder cleanup.

`tests/arrakis_tests.h` contains deterministic logic tests. The main program includes it through a dedicated compiler include directory. Running `--test-game` returns before GLFW window or audio initialization, so tests do not need a desktop. The test code still links into the same executable. The cleanup does not claim to have extracted a

separate test library.

`third_party/glad/` retains the generated loader implementation; `third_party/miniaudio/` retains the audio header and its two-line implementation translation unit. These files are runtime dependencies, not unnecessary downloads. Their license statements and embedded documentation remain intact. `assets/audio/` holds the eight primary sounds requested by the application plus the retained Kenney license notice. Retaining that notice does not establish the provenance or licensing of every unrelated MP3 file; the repository contains no complete per-file sound attribution manifest.

`docs/chapters/` contains this editable explanation. `docs/reference/` preserves the original proposal PDF, `arrakis.png`, and `sandworm.jpg`. `tools/` contains the PDF generator and Python dependency constraints. CMake, the `vcpkg` manifest, README, alternative Visual Studio project, and shared editor settings stay at the root because they are entry points to building or understanding the repository.

The removed folders were `dune`, `spice harvester/`, `low_poly_rocks/`, `ornithopter/`, `spice tank/`, and `thumper/`. They contained unused imported geometry, materials, and textures. Nothing in the renderer loads them; retaining them would imply a nonexistent model-loading pipeline. The old `build/`, `x64/`, and `vcpkg_installed/` folders were generated caches/output rather than source. A new ignored `build/rescue/` is produced when verifying the organized project. It is intentional that verification leaves a runnable build rather than pretending builds never create files.

The unused `stb_vorbis.c`, redundant Ogg delivery sound, and downloaded Kenney fallback pack were removed. The miniaudio implementation never enabled its optional stb Vorbis adapter; the retained selected sounds are WAV or MP3. The audio candidate lists still allow alternate filenames, including Ogg names, but such fallbacks are not included and the default build has no enabled Vorbis decoder. The previous `CODE_EXPLANATION.txt` and historical README sections described an earlier renderer and contradictory controls; the current detailed chapters replace those notes rather than preserving two conflicting manuals. The machine-specific Visual Studio `.user` file and unrelated C/C++ Runner editor settings were removed; the debugger launch was corrected to the actual MSVC executable.

C++ Foundations Used Throughout the Code

An `int` stores integer counts or selections. A `float` stores a single-precision real value such as elapsed seconds, speed, height, or color. A `bool` stores true or false. A structure groups related fields, for example a particle's position, velocity, lifetime, size, and opacity. `enum class` gives names to state choices and prevents accidentally confusing one enumeration with another. `std::vector` is a resizable contiguous container; the code uses it for vertices, indices, workers, groups, and particles. `std::array` is fixed-size. A `std::string` owns text, such as a sound filename or HUD message.

The `g_` naming convention marks global application state. Globals are shared across functions and included headers; they are not automatically thread-safe. Most game/rendering code executes on the main thread. Miniaudio also runs its own processing threads internally. A reference parameter such as `const Mesh&` avoids copying while disallowing changes through that parameter. A non-const reference allows a helper to modify the caller's object. A pointer represents an address and can be null. OpenGL object IDs are integer handles into driver-managed resources, not pointers to their data.

Static variables inside functions retain their values across calls. That is why a seeded random generator produces a deterministic sequence rather than restarting every frame, and why cached uniform locations avoid repeated lookups. At namespace scope, `static` gives internal linkage. `inline` permits definitions in a header to satisfy C++'s multiple-definition rules; it is not a guarantee that the compiler literally substitutes the function's body at every call. `#pragma once` or a matching `#ifndef/#define` header guard prevents the same header from being included twice into one translation unit.

Floating-point literals ending in `f`, such as `0.35f`, specify float precision. Vector arithmetic applies component-wise or according to GLM's defined operators. `std::sin` and `std::cos` expect radians; aircraft headings are stored in degrees and converted before trigonometry or rotations. A `glm::vec2` often represents horizontal coordinates, a `glm::vec3` a world point/direction or RGB color, a `glm::vec4` homogeneous coordinates or RGBA. Normalizing changes a nonzero vector to unit length without changing direction. Clamping restricts a value to a permitted interval.

Linear interpolation `mix(a, b, t)` computes $a * (1 - t) + b * t$; exponential interpolation factors such as `1 - exp(-rate*dt)` implement a time-based approach to a target.

Triangles are the basic filled rendering primitive. A vertex contains position and other per-vertex attributes. An index selects a vertex; indexed triangles reuse data. A shader is a GPU program; GLSL vertex shaders transform points, and fragment shaders decide the color for a covered pixel/sample. A model matrix converts local object coordinates to world space, a view matrix converts the world into camera space, and a projection matrix produces clip-space coordinates. Matrix multiplication order matters. An inverse-transpose normal matrix preserves normal direction under nonuniform scaling. A framebuffer directs rendering to either the screen or off-screen attachments such as the shadow depth texture.

CMakeLists.txt: Lines 1-18, Project and Compilation Units

Line 1 requires CMake 3.20 or newer; an older installation stops configuration rather than attempting unsupported syntax. Line 3 names the project Arrakis and, without a `LANGUAGES` restriction, enables the normal C and C++ compiler discovery needed by the C loader and C++ application. Lines 5-6 request C++17 and require it instead of silently falling back to an older language mode.

Lines 8-18 create an executable target called Arrakis. `src/arrakis.cpp` is compiled as C++; `third_party/glad/glad.c` is compiled as C; `third_party/miniaudio/miniaudio_impl.cpp` is compiled as C++ and instantiates miniaudio's implementation exactly once. The four application headers and the test header are listed as target sources primarily for build dependency tracking and IDE visibility. A header is not an additional independently linked object just because it appears in this list.

CMakeLists.txt: Lines 20-30, Dependency Discovery and Include Paths

Line 20 requires OpenGL and provides the imported `OpenGL::GL` target. On this Windows installation it links the system OpenGL library. Lines 22-24 search for `glad/glad.h`, `GLFW/glfw3.h`, and `glm/glm.hpp`. The specified E-drive directories are hints; `REQUIRED` makes configuration fail when a dependency cannot be found. GLM additionally searches the optional manifest-installed `vcpkg_installed/x64-windows/include` directory. Removing the installed cache does not remove `vcpkg.json`, so it can be regenerated. The successfully verified setup has GLM available at `E:/glm` independently of that cache.

Line 25 searches for a GLFW binary library named `glfw3` or `glfw`. Headers tell the compiler what functions exist, but a library supplies their linked machine code; both are necessary. Lines 26-30 apply discovered include directories only to this executable, using `PRIVATE` rather than publishing them to consumers. The explicit tests include directory resolves `arrakis_tests.h` after its move. The miniaudio include directory resolves `miniaudio.h` from the application audio header; the implementation file also finds it in its own directory. Project headers alongside `src/arrakis.cpp` continue to resolve through normal quoted-include search rules.

Cache overrides such as `-DGLFW_LIBRARY=C:/deps/lib/glfw3.lib` let another machine supply its installation. An include-directory override must point at the parent of `GLFW/`, `glad/`, or `glm/`, not at the individual header file. The retained GLAD C loader was generated for core GL 4.6 even though the application requests a 3.3 context. Its matching declarations are required for compilation; the context's supported version determines which function groups actually load. A randomly different GLAD generation can therefore fail to compile this loader even when the application only uses 3.3 features.

CMakeLists.txt: Lines 32-43, Definitions and Linking

`target_compile_definitions` passes `GLFW_INCLUDE_NONE` to compilation. It asks GLFW not to include a competing system OpenGL header, because GLAD must provide the function declarations and pointers. `PRIVATE` restricts the definition to this executable. `target_link_libraries` links GLFW and `OpenGL::GL`. Miniaudio's platform backend implementation comes from the vendored implementation unit; it is not a separately downloaded miniaudio library. GLM is header-only and does not need a GLM binary here.

The verified Release build emits linker warning LNK4098 about `MSVCRTD` conflicting with other runtime libraries. This is a property of the existing local library/runtime combination, not a missing source file introduced by the reorganization.

The executable and tests succeed, but rebuilding GLFW with the matching release runtime is preferable to hiding the diagnostic. The project does not add `/NODEFAULTLIB` to conceal it.

CMakeLists.txt: Lines 45-56, Runtime Files and Tests

Lines 46-50 add a post-build command to the actual executable target. CMake invokes its own executable using the cross-platform `-E copy_directory` helper, copying the complete `assets/audio` directory under the chosen executable directory. `$(TARGET_FILE_DIR:Arrakis)` is a generator expression evaluated for the selected configuration, so a Visual Studio Release build receives files beneath `Release/assets/audio/`, and Debug receives its own copy. It avoids a hardcoded configuration or user path.

Line 51 sets the generated Visual Studio debugger's working directory to the executable directory. The audio lookup first checks `assets/audio/` relative to its current working directory, then four ancestor directories. This supports root launches, normal build-directory launches, and packaged launches from the executable directory. The implementation still uses relative working-directory lookup, not an absolute path derived from the executable; arbitrary unrelated working directories are not guaranteed to resolve sounds. Failure to resolve a sound does not terminate gameplay.

Line 53 loads CTest integration and the standard `BUILD_TESTING` option. Lines 54-56 register `RescueMissionLogic` only when testing is enabled. The command references the executable target and passes `--test-game`; CMake resolves the right built executable for the selected configuration. `ctest --test-dir build/rescue -C Release --output-on-failure` executes it and reports details on failure. No graphical context is requested for this command.

The Alternative Visual Studio Project

`Arrakis_001.vcxproj` is MSBuild XML. The XML declaration identifies encoding. `<Project DefaultTargets="Build">` selects the default target and the Visual C++ MSBuild namespace. The `ProjectConfigurations` item group defines four pairs: `Debug/Win32`, `Release/Win32`, `Debug/x64`, and `Release/x64`. Each pair records both configuration and platform. The globals record Visual C++ project version 17, project identity GUID, `Win32Proj` keyword, root namespace, and the Windows 10 SDK family. The GUID identifies this project in the IDE; it does not change gameplay.

The first imported Microsoft defaults file supplies standard properties. Four conditional configuration groups choose an Application executable, debug-library selection, toolset v143, Unicode character set, and Release whole-program optimization. Unicode here selects the Windows character-set build property; it does not automatically make every game string Unicode. `Microsoft.Cpp.props` brings in further toolchain settings. Empty extension/shared import groups are standard places for optional tool integration. The four property-sheet import groups allow per-user platform properties if their files exist. The empty user-macros group is a conventional customization point.

The x64 property groups retain E-drive `include/library` paths. `Release/x64` also allows optional `vcpkg`-installed GLM headers; `Debug/x64` uses the laboratory GLM path. These are local-installation conveniences, not portable dependency provisioning. Although Win32 configurations are listed, corresponding 32-bit dependency paths are not configured here; the verified build is x64 through CMake, not a claim that all four standalone configurations are independently tested.

The common item-definition group sets `C++17`, `GLFW_INCLUDE_NONE`, and the relocated `tests/miniaudio` include directories. Its post-build event uses `xcopy /E /I /Y: /E` includes subdirectories, `/I` treats the destination as a directory, and `/Y` overwrites without prompting. The command quotes directories to survive spaces in the project path and places audio below `$(OutDir)`. This event is Windows-specific; the primary CMake copy helper is cross-platform.

Each configuration's compiler group sets warning level 3, SDL checks, relevant console/debug/release macros, and conformance mode. Release additionally enables function-level linking and intrinsic functions. Link settings select a console executable and generate debug information. The x64 linker groups add `glfw3.lib` and `opengl32.lib`, preserving inherited dependencies with `%(AdditionalDependencies)`. `$(...)` is an MSBuild property substitution; `%(...)` refers to inherited item metadata. The source item group compiles the three relocated C/C++ units. The `None` item displays the `vcpkg` manifest without compiling it. Header items display the five relocated application/test headers. The final Microsoft C++ targets import provides actual compile/link targets; the empty extension-target group is a standard trailing integration hook.

`Arrakis_001.vcxproj.filters` is only IDE presentation. Its Source Files, Header Files, and Resource Files filters have stable identifiers and extension lists. Compile entries place the three actual source units under Source Files. Header entries place audio, game, worm, HUD, and tests under Header Files. The manifest is a None item. Filters do not move files, compile resources, or alter output; changing only the filter file never repairs a broken source path in the project itself.

Shared Editor and Dependency Configuration

`.vscode/c_cpp_properties.json` contains one IntelliSense configuration named `Win32-MSVC`. Its recursive workspace include path sees relocated headers; its additional E-drive paths expose installed GLFW/GLAD and GLM. `compilerPath` selects `cl.exe`, C language mode is `C17`, C++ language mode is `C++17`, and IntelliSense uses the Windows MSVC x64 model. The final version value 4 identifies the extension's settings schema, not the compiler version. These settings assist editing and do not replace CMake's real compilation flags.

`.vscode/launch.json` uses the debugger schema version 0.2.0. Its single configuration is named `Arrakis (CMake Release)`, has `type: cppvsdbg` for the Visual Studio Windows debugger, and `request: launch` to start rather than attach. The empty argument array launches normal gameplay. `stopAtEntry: false` avoids an automatic initial breakpoint. The integrated terminal displays console messages, the working directory is `${workspaceFolder}`, and the program path selects `build/rescue/Release/Arrakis.exe`. This configuration assumes that Release has already been built; it does not silently build or select a Debug executable.

`vcpkg.json` is a JSON manifest. Its `dependencies` array contains only `glm`; it does not install GLFW, GLAD, or miniaudio. Its `builtin-baseline` records a specific `vcpkg` registry revision for reproducible version selection. A manifest's existence alone does not run installation without a configured `vcpkg` workflow/toolchain. The existing build prints a notice that manifest mode is disabled; this is not a build failure because independently discovered GLM satisfies the dependency.

Every .gitignore Rule and Why It Exists

Git ignores are repository hygiene, not deletion instructions and not security boundaries. A pattern never removes a tracked file or prevents the program from using an ignored file already on disk. A leading `/` anchors the pattern to the repository root. A trailing `/` targets directories. `*` matches arbitrary text. A comment beginning with `#` has no matching effect.

`/build/`, `/build-*/`, `/out/`, `/x64/`, and `/x86/` cover root build/output folders. `Debug/`, `Release/`, `RelWithDebInfo/`, and `MinSizeRel/` exclude generated configuration directories at any depth. `CMakeFiles/`, `CMakeCache.txt`, `cmake_install.cmake`, `install_manifest.txt`, `CTestTestfile.cmake`, `Testing/`, and `_deps/` cover CMake discovery state, generated scripts, test output, and fetched dependencies.

`CMakeUserPresets.json` is a personal configuration file; a shared `CMakePresets.json`, if later added, remains trackable. `/vcpkg_installed/` excludes reproducible installed-package copies, while `vcpkg.json` remains included.

`*.o` and `*.a` are common Unix object/static-library outputs. `*.exe`, `*.dll`, `*.so`, `*.so.*`, `*.dylib`, and `*.lib` cover executables/shared/static libraries on Windows, Linux, and macOS. `*.pdb` and `*.idb` are debug databases; `*.ilk` is incremental-link state; `*.exp` is exported-symbol linker output; `*.pch` is a precompiled header; `*.tlog` is MSBuild tracking; `*.obj.enc` is Edit-and-Continue object state; `*.exe.recipe` is a generated executable recipe; `*.log` is log output. The broad old `*.obj` rule is deliberately absent because Wavefront 3D model files use the same extension as Windows object files. MSVC object files belong in the already ignored build directories rather than forcing all future model assets invisible to Git.

`.vs/`, `*.vcxproj.user`, `*.suo`, `*.user`, `*.VC.db`, `*.VC.VC.opendb`, and `.vscode/ipch/` exclude user-specific IDE caches and preferences. Shared `.vcxproj`, `.vcxproj.filters`, `.sln`, `launch`, and IntelliSense files are not globally hidden. `__pycache__/`, `*.py[cod]`, and `.venv/` exclude Python bytecode or a local virtual environment. `/docs/.cache/` provides an ignored place for generated documentation intermediates; the requested PDF is intentionally not ignored. `Thumbs.db`, `ehthumbs.db`, `Desktop.ini`, and `.DS_Store` cover operating-system folder metadata. `*~`, `*.swp`, and `*.swo` cover common editor backups/swap files. No blanket PDF, PNG, JPG, WAV, or MP3

pattern hides required documentation or assets.

Verified Cleanup Behavior and Remaining Limits

The organized project was configured from a clean build directory and built in MSVC Release/x64. The alternative standalone Visual Studio project was also built successfully in Release/x64, with its output and intermediates explicitly directed beneath `build/native/` and `vcpkg` integration disabled for that check. Its post-build event copied all eight sounds and the retained license. `RescueMissionLogic` passed. The normal render, breach, mouse-steering/camera, and pursuit smoke tests each rendered 120 frames and reported success on an Intel Iris Xe OpenGL 3.3 driver. An additional smoke run from the executable directory also loaded every selected sound. These checks exercise actual relocated runtime assets rather than only searching source text for filenames. The standalone build additionally reports a vendor warning C4244 at `miniaudio` line 80532 about narrowing an unsigned 64-bit value to 32 bits; the vendored code is retained unchanged rather than modifying library internals during cleanup.

The post-build asset copy is not an installer. It is triggered by a build of the executable target, and does not continuously watch asset edits. Rebuild the target or recopy assets if only sound files change after a previous build. Tests validate deterministic mechanics and finite scripted rendering windows, not every possible human flight path. No network, save file, persistent leaderboard, imported-model loader, cloud sky renderer, or image-based worm texture is implemented. Those distinctions are documented so the explanation remains a description of existing functionality rather than an aspirational feature list.

Chapter 2: Terrain, Particles, Procedural Meshes, and the Renderer

Reading This Chapter

This chapter explains **original arrakis.cpp lines 1-967**, captured before the source file was reorganized into `src/arrakis.cpp`. All numbered line-range headings refer to that original snapshot, not to whichever line numbers a later editor displays. The final covered line, 967, is blank; the last actual declarations are the rock colors on lines 965-966. Source listings are supplied separately, so the explanations below describe the code rather than replacing explanation with long source quotations.

The ranges follow source order. Every nonblank line in the requested interval belongs to a numbered subsection, including file comments, preprocessor directives, declarations, shader-string delimiters, and closing braces. Blank lines between ranges provide visual separation and do not execute. A brace starts or ends a scope: the body of a function, loop, conditional, structure, initializer, or shader. A semicolon finishes a declaration or statement. Where several closing braces occur together, they close the previously described nested operations rather than introduce hidden work.

For a beginner, it helps to separate three kinds of activity:

- **CPU-side C++** constructs terrain samples, particle states, vertex arrays, and rendering commands. Its ordinary functions execute on the processor.
- **OpenGL API calls** ask the graphics driver to create objects, upload bytes, configure state, or draw. An OpenGL object identifier is an integer handle, not the actual vertex data or texture pixels.
- **GPU-side GLSL** is source text embedded in C++ strings. The driver compiles that text into shader programs. Vertex shaders run on vertices; fragment shaders compute results for rasterized fragments, which are candidates for image pixels.

The terrain uses a Y-up convention: X and Z run across the ground, while Y is height. A `glm::vec2` contains two numbers, `vec3` three, and `vec4` four. A vector can represent a position, direction, color, or packed record depending on context. `glm::mat4` is a four-by-four transformation matrix. Coordinates with an extra `w` component are **homogeneous coordinates**: using `w = 1` allows a matrix to translate a point, while a direction normally uses `w = 0` so translation has no effect.

`float` is a floating-point number, `int` an integer, and `bool` a true-or-false value. The suffix `f` marks a C++ numeric literal as a `float`, such as `0.4f`; GLSL does not need that suffix. `const` prevents ordinary reassignment. A reference, written `&`, refers to an existing object instead of making a copy. `const T&` lets a function inspect an object without modifying it. `auto` asks the compiler to infer a type. `std::vector<T>` is a resizable, contiguous collection of values of type `T`.

The mathematical helpers recur throughout the renderer. `normalize(v)` divides a nonzero vector by its length, producing a direction of length one. `dot(a, b)` adds componentwise products; for normalized directions it equals the cosine of their angle. `cross(a, b)` produces a perpendicular vector whose orientation depends on argument order. `mix(a, b, t)` is linear interpolation, $(1-t)a + tb$. `clamp(x, a, b)` confines a value to the interval from `a` to `b`. `smoothstep(a, b, x)` first clamps $t = (x-a)/(b-a)$ to $[0, 1]$, then returns $t*t*(3-2*t)$, a smooth transition with zero endpoint slopes. `sin` and `cos` take radians; one full turn is 2π , approximately 6.2831853 radians.

Scope caution: these lines define reusable renderer machinery. They do not yet contain the main frame loop, complete aircraft or harvester assembly, input callbacks, all uniform assignments, resource destruction, or the actual particle draw call. A declaration here does not prove that a later feature is enabled, nor does a shader uniform declaration provide its runtime value. The discussion distinguishes exact values visible in this interval from values that must be supplied elsewhere.

File Setup and Shared State

1. Original Lines 1-43: File Banner, Feature Claims, and Control Notes

Every line in this range is a C++ `//` comment. The compiler ignores the banner and its descriptive text. Lines 1 and 43 are decorative separators. Lines 2-3 name the project, its rescue-game theme, and its laboratory course. Lines 5-7 summarize its intended presentation and claim that geometry is generated from primitives rather than loaded from `.OBJ` files. The primitive builders explained later support the procedural-geometry description; these comments are not a runtime prohibition against adding other assets.

Lines 9-28 list claimed visual features. The aircraft description names eight wings, a faceted cockpit, turbine intakes, thruster coloration, and banking. The harvester description names four crawler units, a front drum, an upper refinery structure, floodlights, and funnels. The tank description names pressure vessels, domed ends, supporting trusses, gauges, and pipes. These assemblies are outside the present line interval; the meshes and materials here are building blocks for them.

The terrain comment says "140x140 vertex heightfield" and "analytical normals." The actual default terrain has **140 by 140 cells and 141 by 141 vertices**, because both vertex loops include their final endpoints. Its normals are calculated using four nearby height samples, a finite-difference method, not exact symbolic differentiation. The atmospheric comment says more than 2,000 particles; the actual pool constant is 2,400. The lighting description is broadly recognizable in the later shaders, but its sand diffuse equation is a particular 0.35-wrap expression rather than the canonical squared half-Lambert formula. The shadow filter is specifically a 5-by-5 manual PCF filter.

Lines 30-42 list user-facing controls: Enter starts or advances missions; mouse hover steers; W/S and A/D move; Q/E change altitude; Left Shift boosts; Space hovers or operates rescue actions; P/R pause or retry; arrow keys steer or adjust camera elevation; C switches camera mode; F requests wireframe; F11 requests fullscreen; Escape quits. This comment does not implement those actions. Within this chapter, only the key-state storage and the particle branch that checks Space are present. Keeping descriptive comments separate from executable logic prevents assuming that the banner itself enforces behavior.

2. Original Lines 45-59: Graphics, Mathematics, and Standard-Library Includes

`#include` is a preprocessor instruction that makes declarations from another header available before C++ compilation. Angle brackets normally select library headers through configured include paths. Line 45 imports GLAD's OpenGL declarations and function-loading interface. Modern OpenGL functions need to be loaded for the active context; merely including this header does not load them. Line 46 imports GLFW, which supplies window/context management, key codes, and the `glfwGetTime()` clock used below.

Line 48 imports GLM vector and matrix types. Line 49 adds transformation helpers such as translation, scaling, rotation, and projection-related matrix operations. Line 50 supplies `glm::value_ptr`, which exposes the contiguous numerical storage needed when passing GLM objects to OpenGL uniform functions. Whether all mathematical constants used later are made available transitively depends on the project's GLM configuration and headers; these lines do not contain an explicit constants-header include.

Lines 52-59 include eight standard C++ facilities. `<iostream>` provides `std::cerr` and stream output for shader/framebuffer errors. `<vector>` supplies dynamic collections. `<cmath>` supplies trigonometry, absolute values, and other math operations. `<random>` supplies the Mersenne Twister generator and uniform real distributions. `<algorithm>` supplies operations such as `std::swap`, used to correct rock triangle orientation. `<string>` provides strings, `<fstream>` file streams, and `<stdint>` fixed-width integer definitions. Some of these facilities serve later parts of the same translation unit; being included here does not imply that every header is directly used before line 967.

These directives have no visible rendering effect by themselves. They tell the compiler what names and types mean. Actual context creation, function loading, and initialization must happen before the later OpenGL calls execute.

3. Original Lines 61-67: Window and Display Globals

Lines 61-63 are a section-label comment. `g_scrW = 1280` and `g_scrH = 720` establish initial display dimensions. Their ratio is $1280/720 = 16/9$, approximately 1.7778. These values can later be changed by window or framebuffer callbacks; the declarations do not guarantee that the physical framebuffer permanently has this resolution.

`g_isFullscreen = false` records that startup is not fullscreen. `GLFWwindow* g_window = nullptr` declares a pointer to a GLFW window object and initializes it to the null pointer, meaning that no valid window object is referenced yet. A pointer stores an address-like reference; it is not a copied window. A later successful window-creation call must assign it before window operations can safely use it.

The `g_` prefix is a naming convention for shared globals, not a C++ keyword. These variables are defined at file scope, so functions later in the translation unit can access them. Shared state is convenient in a compact teaching project but couples callbacks, simulation, and rendering: an incorrect dimension update can affect projection or viewport behavior elsewhere. This range stores configuration only and neither creates a window nor sets an OpenGL viewport.

4. Original Lines 69-87: Keyboard, Camera, Flight, and Wing State

Lines 69-71 introduce camera and flight state. `g_keys[1024] = {}` is a fixed array of 1,024 Boolean entries, all initialized to false through value initialization. A later input callback can mark a key as pressed or released; this array does not itself poll the keyboard. The Space particle branch indexes it using GLFW's Space key constant. General input code must still avoid out-of-range key indices.

`g_wireframe = false` records a filled-rendering preference. `g_camMode = 0` selects the comment's cinematic chase mode; values 1 and 2 represent cockpit/close and overhead/tactical modes. These integers are a convention, not a type-safe enumeration or validation mechanism. `g_camOrbitPitch = 0.0f` stores an initial camera-orbit pitch offset.

The flight comment at line 77 introduces `g_ornPos(0, 18, 0)`, placing the aircraft initially at $X=0, Y=18, Z=0$. This is a world-space position, not automatically a terrain-relative altitude. `g_ornVel(0.0f)` uses GLM's scalar constructor to set all three velocity components to zero. `g_ornYaw`, `g_ornPitch`, and `g_ornRoll` start at zero degrees. Yaw is heading, pitch is nose tilt, and roll is banking around the forward axis. The exact rotation order of a model is determined by later transformation code rather than these names alone.

`g_ornSpeed = 0` stores a scalar cruise-speed state separate from the velocity vector. `g_isBoosting = false` records that boost is inactive. None of these declarations integrates acceleration or computes flight dynamics; they supply the initial state used by later logic. Line 86's wing comment precedes `g_wingPhase = 0`, an animation-phase accumulator. Its declaration alone specifies neither frequency nor amplitude and does not enforce the "movie-accurate" claim. The visible implementation should be explained as animated mathematical geometry rather than physical aerodynamics.

5. Original Lines 89-99: Harvester Coordinates and Tank Instances

The harvester comment introduces `g_harvX = -80` and `g_harvZ = 15`. These are initial horizontal coordinates. No harvester Y coordinate appears here because later code can derive elevation from terrain. The exact horizontal distance of this point from the origin is $\sqrt{80^2 + 15^2}$, approximately 81.39 world units.

Lines 93-98 define `SpiceTankInstance`, a small C++ record grouping three related properties. `pos` is a three-component placement vector, `yaw` is a scalar heading, and `scale` is a scalar size multiplier. Their declarations have no in-class default initializers. Code constructing a tank must provide meaningful values before using them; one should not read these members as automatically containing a ready-to-render placement. The opening and closing braces define the structure's member list, and the trailing semicolon finishes the type declaration.

`std::vector<SpiceTankInstance> g_tanks` defines a initially empty collection of tank instances. A structure defines what one record looks like, whereas a vector stores zero or more actual records. The tank geometry is not duplicated here; later code can reuse the same primitive meshes with different transformations and material settings. This separates an object's placement data from the GPU objects used to draw it.

Terrain Height and Normal Queries

6. Original Lines 101-118: `rawDuneHeight` and the Undisturbed Height Equation

Lines 101-104 label the continuous dune function. `rawDuneHeight(float x, float z)` takes horizontal coordinates by value and returns one floating-point elevation. It does not allocate a mesh; any subsystem can ask for a height at any coordinate, including coordinates beyond the finite rendered terrain. The code sums deterministic trigonometric patterns, not random terrain noise or a physical wind-erosion simulation.

The primary swells are $h1 = 14 \cdot \sin(0.009 \cdot x + 0.004 \cdot z)$ and $h2 = 9.5 \cdot \cos(0.004 \cdot x - 0.012 \cdot z)$. Their amplitudes are 14 and 9.5 units. The arguments combine X and Z, so each pattern runs diagonally rather than along only one axis. For the first wave, the horizontal wave-vector length is $\sqrt{0.009^2 + 0.004^2}$, approximately 0.0098489 radians per unit, producing a perpendicular wavelength of about $2 \cdot \pi / 0.0098489 = 637.95$ units. The second wavelength is about 496.73 units. These are broad landscape undulations.

The ridge starts with $s = \sin(0.028 \cdot x + 0.016 \cdot z)$, transforms it to $r = 1 - \text{abs}(s)$, and produces $5 \cdot r \cdot r$. Since $\text{abs}(s)$ lies between zero and one, the ridge contribution lies between zero and five. Squaring concentrates its elevation around locations where the original sine is zero. Taking an absolute value halves the repetition period in the phase and introduces a derivative cusp at those zero crossings. Despite the "asymmetric windward & leeward" comment, this expression does not explicitly distinguish a windward side from a leeward side; it creates a symmetric folded ridge pattern.

$h3 = 1.8 \cdot \sin(0.065 \cdot x + 0.038 \cdot z)$ adds smaller, shorter undulations with a wavelength of approximately 83.45 units. The return statement sums $h1 + h2 + \text{ridge} + h3 - 4$. The minus-four term shifts the overall height down. Independent term bounds give a conservative range from -29.3 to 26.3, though the waves do not necessarily reach all extreme values at the same point. At $(0, 0)$, the sine terms vanish, $h2 = 9.5$, and $\text{ridge} = 5$, so the returned height is 10.5. The closing brace ends the query; there is no state update or temporal animation in this function.

7. Original Lines 120-130: `getDuneHeight` and the Flattened Landing Terrace

`getDuneHeight(x, z)` begins with the raw height, then modifies it near a landing pad. The local static `const` array is initialized only once, when this function first reaches its declaration, and remains available on later calls. It contains one `glm::vec3`: `{55, 55, rawDuneHeight(55, 55)}`. Here the first two components are **horizontal X and Z**, and the third is the target height. This is a special packed convention, not the normal world-position convention (x, y, z) .

For this one center, `center.x = 55`, `center.y = 55`, and `center.z` is approximately 13.3066. Converting `center` to `glm::vec2` keeps its first two components, correctly obtaining the horizontal pad center $(55, 55)$. Conversely, the height blend deliberately uses `center.z`, the stored target elevation. Misreading that component as a horizontal coordinate would make the function seem incorrect when it is actually using a compact record layout.

The range-based loop uses `const auto& center`, so each iteration reads an existing array element without copying or modifying it. The ternary `center.x == 55 ? 15 : 10` chooses radius 15 for the present entry. The 10-unit alternative is dormant with this one-element array; it is not a second existing terrace. The equality test works for the exactly initialized value 55 but is an ad hoc rule tied to position rather than an explicit radius field.

Let d be the horizontal distance from (x, z) to $(55, 55)$. The blend weight is $b = 1 - \text{smoothstep}(15, 25, d)$. Inside radius 15, $b=1$ and the height becomes exactly the stored plateau height. Beyond radius 25, $b=0$ and raw terrain is unchanged. In between, the cubic transition blends the two. At radius 20, $b=0.5$, so the result is their average. `glm::mix(height, center.z, blend)` implements that interpolation. The return statement supplies the final height after the loop. Evacuation sites are not flattened by this array, matching the comment's distinction from the landing pad.

8. Original Lines 132-139: `getDuneNormal` and Central Finite Differences

`getDuneNormal(x, z)` estimates which direction the surface faces. A surface normal is perpendicular to the local ground; lighting uses it to decide how strongly the surface faces the sun. The sampling offset is `eps = 0.4`, giving a full difference baseline of $2 \cdot \text{eps} = 0.8$ units.

The function evaluates the final, terraced height at four points. h_L samples X minus 0.4, h_R X plus 0.4, h_D Z minus 0.4, and h_U Z plus 0.4. Calling `getDuneHeight` rather than `rawDuneHeight` means the normal includes the landing-pad blend. Approximate derivatives are $(h_R - h_L)/0.8$ and $(h_U - h_D)/0.8$.

For a heightfield $y=h(x, z)$, an upward-facing unnormalized normal is $(-dh/dx, 1, -dh/dz)$. The code multiplies all components by 0.8 to avoid two explicit divisions, constructing $(-(h_R - h_L), 0.8, -(h_U - h_D))$, then normalizing. Multiplying a nonzero vector by a positive scalar does not change its normalized direction. On a perfectly flat surface, both differences vanish and the result is $(0, 1, 0)$.

This is **finite-difference estimation**, not an analytical derivative. It samples across sharp ridge features and the terrace transition, producing a smoothed estimate over the baseline. Four height queries are needed per normal. The positive Y component ensures a nonzero input even on flat ground, so this particular normalization does not encounter a zero vector. The method also differs from computing a triangle's geometric face normal: the rendered mesh samples terrain every five units by default, while this normal samples a much smaller 0.8-unit baseline. Later interpolation gives smooth shading that need not exactly match each triangle plane.

9. Original Lines 141-144: Local Audio, Game, and Test Headers

Lines 141-143 include `arrakis_audio.h`, `arrakis_game.h`, and `arrakis_tests.h` using quotes, which select project-local headers through the configured search rules. They appear after the shared flight globals and terrain-query functions. That placement makes earlier declarations visible to code introduced by these headers, an important dependency in this single-translation-unit organization.

The later particle update uses names such as `wormAttackTime()`, `wormPosition()`, `harvesterForward(...)`, and `g_mission.harvesterYaw`, supplied through the game's header-level code rather than declared in the immediate particle section. This chapter explains how those values are consumed, not the internal mission rules that produce them. Audio and test internals likewise belong to their own chapters. Line 144 is a blank separator.

An include is textual preprocessing, not a call that executes the entire game at that moment. Definitions brought in by a header can still create globals or functions as part of the resulting translation unit, but runtime actions occur only when the resulting code is initialized or invoked. This distinction matters when following source order: declaration visibility follows includes, whereas frame-by-frame control flow follows function calls.

Wind and Particle Simulation

10. Original Lines 145-162: Wind Constants, SandParticle, and the Pool

Lines 145-147 label the particle system. `WIND_DIR` normalizes $(-0.92, -0.04, 0.38)$. The original vector length is $\sqrt{0.9924}$, approximately 0.99619, so the normalized result is approximately $(-0.92352, -0.04015, 0.38145)$. Most wind therefore travels toward negative X , somewhat toward positive Z , and slightly downward. `WIND_BASE_SPEED = 18` supplies the nominal speed multiplier in world units per second, assuming the caller passes `dt` in seconds.

`SandParticle` groups six simulation/rendering properties. `pos` is world position; `vel` is velocity; `life` is remaining lifetime; `maxLife` records a reference lifetime; `size` is a scalar billboard size; and `alpha` is an opacity multiplier. These members have no explicit defaults in the structure. The initialization and respawn functions assign the fields they need. `life` is not a normalized progress percentage, and `maxLife` does not automatically affect opacity; later draw preparation must decide whether to use their ratio.

`MAX_PARTICLES = 2400` fixes the intended pool size. `g_particles` starts as an empty vector and is resized by `initParticles`. A fixed pool lets updates recycle records instead of continuously allocate and remove individual particles. These particles model visible dust, not conserved physical sand grains: their positions and velocities are manually reassigned, they have no mass, and they do not collide with one another. The section's closing structure brace and semicolon complete the record type rather than performing initialization.

11. Original Lines 163-179: `initParticles` and Reproducible Initial Values

`initParticles()` resizes the vector to 2,400 entries. It then constructs a local `std::mt19937` generator with seed 1337. This is a deterministic pseudorandom engine: repeated initialization starts the same engine sequence. Exact samples from `std::uniform_real_distribution` can vary across standard-library implementations, so reproducibility should not be overclaimed across every platform. The generator exists only for this initialization call.

Four distributions describe desired ranges: horizontal position from -120 to 120, Y from 0.5 to 25, lifetime from 1 to 4, and wind-speed factor from 0.8 to 1.4. Uniform real distributions conventionally produce values in a half-open range, although floating-point endpoint behavior should not be used as a safety guarantee. The range-based loop obtains each particle as a mutable reference, `auto& p`, so assignments change the vector entry directly.

The position constructor draws two horizontal values and one vertical value. It does **not** add the dune height; an initial particle may therefore start under a hill and be corrected during update. The velocity is the normalized wind multiplied by `18*speedFactor`, giving nominal speeds from 14.4 to 25.2. `maxLife` and `life` are drawn independently. Consequently a newly initialized particle can have `life > maxLife`; these are not initially guaranteed to form a ratio in $[0, 1]$.

The engine's raw integer output modulo 100 gives values 0-99. Size becomes $0.18 + 0.003 * n$, ranging from 0.18 to 0.477. Alpha becomes $0.25 + 0.0035 * n$, ranging from 0.25 to 0.5965. Modulo sampling has a small distribution bias unless the engine range divides evenly by 100. These are deliberate visual variations, not real-distribution draws. The closing loop brace finishes all particle assignments, and the function brace finishes initialization; no GPU instance buffer is uploaded here.

12. Original Lines 181-190: `updateParticles`, the Gust Clock, and Integration

`updateParticles(float dt, glm::vec3 centerPos, glm::vec3 harvPos)` advances the pool. The elapsed step `dt` is copied as a scalar; both positions are copied as small vectors. `centerPos` is the focus/player position used for distance tests and respawning, while `harvPos` anchors crawler dust. The function assumes useful, nonnegative time steps; it does not clamp or validate `dt` here.

The gust multiplier is $1 + 0.35 * \sin(\text{glfwGetTime}() * 1.8)$. It ranges from 0.65 to 1.35 and repeats every $2 * \pi / 1.8$, approximately 3.491 seconds. The clock is GLFW's absolute elapsed time, cast from its wider floating type to `float`. Gust timing therefore follows that external clock rather than an accumulator local to the particle function. If simulation updates are paused elsewhere while the clock continues, the gust phase can change before updates resume.

The local static `std::mt19937 rng(1984)` is initialized once and retains its state across calls, unlike the initialization engine. Horizontal respawn offsets use -100 to 100, and vertical offsets use 0.2 to 32. The indexed loop visits every vector entry, casting its size to `int`; with a 2,400-entry pool this conversion is safe in practice, though it is not a generic solution for arbitrarily enormous vectors.

`p.life -= dt` decreases remaining lifetime. `p.pos += p.vel * (gust * dt)` performs a forward-Euler position update with gust-scaled displacement. Gust does not modify the stored velocity; it scales movement during this step. This multiplier affects every particle class, including worm spray and downwash, not only ordinary wind dust. There is no acceleration integration, drag calculation, or gravity term in this opening part of the update.

13. Original Lines 192-204: Ground Response and Respawn Eligibility

The ground-collision comment introduces a height query at the particle's current X/Z. If Y is below `groundY + 0.2`, the code places it exactly 0.2 units above the sampled terrain and changes vertical velocity to $\text{abs}(\text{oldV}_y) * 0.5 + 0.8$. A downward velocity of -2 becomes +1.8; an upward velocity of +2 also becomes +1.8 if the particle still lies below the threshold. This is a visual rebound-and-lift rule, not an energy-conserving collision. There is no later gravity here to pull the particle down again.

The distance test converts both positions to horizontal two-component coordinates and uses Euclidean distance, ignoring vertical separation. Thus a particle high above the aircraft can still be horizontally near it. Respawning occurs when `life <= 0`, or when the particle is beyond 160 units **and** its index is divisible by neither 4 nor 3. Operator

precedence makes the nested parentheses important: the far-distance exemptions do not protect a particle whose lifetime has expired.

The `i % 4 != 0 && i % 3 != 0` condition exempts indices reserved for possible crawler or worm effects from distance-only recycling, even if those effects are currently inactive. Among 2,400 indices starting at zero, 1,200 are divisible by 3 or 4, by inclusion-exclusion: 800 plus 600 minus 200. These 1,200 still respawn on lifetime expiry. The remaining 1,200 are subject to both expiry and distance recycling.

Inside the respawn block, lifetime is $2 + 0.02 * n$ for integer n from 0 to 99, giving 2.00-3.98 seconds. `maxLife` is then assigned that same value, unlike the independent initial samples. The particle's old state has already been moved and ground-corrected before it is recycled. Subsequent branches replace its position, velocity, size, and opacity based on effect priority.

14. Original Lines 205-214: Crawler-Plume Respawning

The comment says "Half particles spawn upwind" and mentions crawler dust, but exact proportions depend on the ordered branches and their time conditions. The first branch accepts indices divisible by four when `wormAttackTime() < 12`. It has highest priority. A particle qualifying here cannot also enter the worm or Space branches on this respawn. The comparison includes negative attack-time values as well as positive ones below 12; the meaning of those values is defined by mission logic elsewhere.

`forward = harvesterForward(g_mission.harvesterYaw)` obtains the harvester's heading direction. `right = cross(forward, (0, 1, 0))` obtains a perpendicular lateral vector. Its sign follows the heading convention in `harvesterForward`; the variable's name should not replace checking that convention. The code does not normalize `right` here, so a unit lateral displacement assumes the supplied forward vector is appropriately normalized and horizontal.

The new position is the harvester position, minus four units along forward, plus a lateral offset, plus a vertical offset. The lateral value is $-4 + 0.1 * n$ with n from 0 to 79, so it ranges from -4 to 3.9. The vertical offset is $1 + 0.1 * n$ with n from 0 to 29, ranging from 1 to 3.9. This creates a rectangular region behind and above the harvester rather than positions tied to individual tread geometry.

Velocity combines half-strength wind, `WIND_DIR*9`, a two-unit-per-second backward component, $-\text{forward} * 2$, and +2.5 vertical lift. It is not renormalized, so its total speed depends on the vector sum. Alpha is fixed at 0.55 and size at 0.45. The branch does not resample terrain after spawning; its placement is based on the supplied harvester position, and the next update's ground check will correct a below-ground result.

15. Original Lines 215-223: Worm Dust, Angular Samples, and Attack-Dependent Spray

The `else if` selects indices divisible by three when `wormAttackTime() < 18`, provided the preceding crawler branch did not run. A multiple of both three and four will therefore use crawler dust while the earlier time condition is active; after that condition fails, it can use worm dust. These are index-based visual allocations, not independent emitter objects.

`wormPosition()` supplies the effect center. The angle $a = (\text{rng}() \% 10000) * 0.0006283185$ spans approximately one full turn in 10,000 discrete steps, because the multiplier is $2 * \pi / 10000$. Radius is $10 + 0.01 * n$, where n is 0-1499, giving 10-24.99. Uniformly sampling radius is not uniform sampling of disk area; moreover, this distribution is an annular region, not a filled disk.

The position offset is $(\cos(a) * \text{radius} - 0.01 * m, 0, \sin(a) * \text{radius})$ with m from 0 to 2199. The extra X-only subtraction ranges from 0 to 21.99, creating a negative-X trail rather than a symmetric ring. After constructing X/Z, the code overwrites Y with local terrain height plus 0.8, so worm dust begins near the undisturbed CPU terrain even if the vertex shader later visually depresses that area.

Velocity uses radial horizontal speed 7, vertical speed 10 when attack time is greater than zero or 2 otherwise, then adds `WIND_DIR*4`. Size similarly switches between 5.5 for positive attack time and 2.2 otherwise. Alpha is fixed at 0.22. These large translucent billboards depict disturbed sand, not individual grains. Repeated `wormAttackTime()` calls are separate function evaluations; the code does not cache a single time for all comparisons in this update.

16. Original Lines 224-228: Space-Key Downwash Respawning

The next `else if` requires an index divisible by five and `g_keys[GLFW_KEY_SPACE]` to be true, while all earlier branches must have failed. It responds to the stored key-state flag rather than querying GLFW directly. Because this code is inside the respawn block, pressing Space does not instantly reposition all qualifying particles; the effect appears as particles expire or satisfy their distance-recycling condition.

The angle is `(rng()%1000)*0.006283185`, approximately $2\pi/1000$ times a 0-999 integer. The new position is centered on `centerPos` with a four-unit horizontal radius and a vertical offset of -4. It is therefore a circular emitter four units below the focus position, not a surface sample under each rotor or a simulation of actual wing airflow.

Velocity is `(11*cos(a), 1.5, 11*sin(a))`. Its horizontal magnitude is exactly 11 in ideal arithmetic; including vertical lift gives a speed of `sqrt(121+2.25)`, approximately 11.102. It has no wind term at assignment, but the shared gust multiplier still scales its motion in later updates. Size is 1.8 and alpha 0.18, both assigned on the same source line. The low opacity and large size create a broad dust appearance.

No local height adjustment occurs in this branch. If the aircraft is low enough, the new particle can be below the ground until the next call applies the ground correction. The branch also does not check mission hover eligibility, winch state, or actual altitude beyond the supplied position: its visible trigger in this interval is simply Space plus index priority.

17. Original Lines 229-240: Ordinary Upwind Respawning and Update Closure

The final `else` handles every respawn not claimed by crawler, worm, or downwash effects. `upwind = -WIND_DIR*90` offsets the emitter opposite the nominal wind. Using the normalized direction, this is approximately (83.117, 3.614, -34.331). Because the wind has a slight downward component, going upwind also moves the starting point upward.

The new position is `centerPos + upwind + (randomX, randomY, randomZ)`, with horizontal offsets from -100 to 100 and a vertical offset from 0.2 to 32. The vertical value is relative to the center position, not directly relative to terrain. The following height query checks `if (p.pos.y < gy)` and, only then, sets `Y` to `gy+1`. A particle already slightly above the surface is not raised to a full unit; this differs from the earlier unconditional collision threshold of terrain plus 0.2.

Velocity is wind times $18*(0.85+0.01*n)$ with `n` from 0 to 39. The stored speed therefore ranges from 15.3 to 22.32. After gust scaling, its instantaneous displacement speed can range from about 9.945 to 30.132 across those independent extremes. Alpha is 0.28 and size is 0.22. Recycling overwrites any earlier plume or spray settings so the record becomes an ordinary wind particle again.

Line 237 closes the ordinary branch, line 238 closes the respawn conditional, line 239 closes the particle loop, and line 240 closes the function. No particle sorting, mesh upload, alpha blending, collision with objects, or resource allocation occurs in this update. Its responsibility is CPU simulation state only.

Mesh Records and GPU Upload

18. Original Lines 242-258: Vertex, Mesh, and Indexed Drawing

Lines 242-245 introduce procedural primitives and reiterate that shapes are mathematically built. `Vertex` contains `pos`, `normal`, and `uv`. Position places a vertex in a mesh's local coordinates. A normal provides shading orientation and may differ from a geometric face normal when smoothing is desired. UV is a two-component surface coordinate used by shaders; it does not require an image texture to exist. In this renderer, particle UVs define circular opacity, while the surface shader's patterns chiefly use world coordinates instead.

Mesh stores three OpenGL handles initialized to zero: `VAO`, `VBO`, and `EBO`. A **vertex buffer object** stores vertex bytes. An **element buffer object** stores indices that select vertices to form primitives. A **vertex array object** remembers attribute layout and associated buffer state. It is not a second copy of the geometry. Handle zero means no generated object has yet been assigned to that field.

`GLsizei indexCount = 0` holds the number of indices to draw, not the number of vertices or triangles. `GLenum drawMode = GL_TRIANGLES` selects independent groups of three indices by default. For example, 36 indices

represent 12 triangles when this mode is used. `GLsizei` and `GLenum` are OpenGL-defined types, communicating the expected integer category to the API.

The record has no destructor and no ownership-enforcing copy rule. Copying a `Mesh` copies its handles rather than duplicating GPU storage. Returning one from a builder is convenient, but automatic scope exit will not call `glDeleteBuffers` or `glDeleteVertexArrays`. Any resource cleanup must be handled explicitly elsewhere. This is a lightweight handle container, not an RAII resource wrapper.

19. Original Lines 260-274: `uploadMesh`, Buffer Creation, and Storage

`uploadMesh` accepts constant references to vertex and unsigned-index vectors. It can inspect their contiguous data without copying whole CPU arrays or changing them. A local `Mesh m` applies the structure's default member initializers. The index count is obtained by casting `indices.size()` to `GLsizei`; extremely large input would need overflow checks, but these procedural meshes are small enough for the intended type.

The three `glGen...` calls request one vertex-array handle, one vertex-buffer handle, and one element-buffer handle, writing each generated name through the address of its member. Generation is not a geometry upload. Binding `m.VAO` makes it the active vertex-array state record. Subsequent element-buffer and attribute configuration will belong to that VAO.

`glBindBuffer(GL_ARRAY_BUFFER, m.VBO)` selects the vertex buffer as the target for the next upload. `glBufferData` allocates/copies `verts.size()*sizeof(Vertex)` bytes from `verts.data()`, with `GL_STATIC_DRAW` as a driver usage hint. That hint suggests infrequent replacement and frequent drawing; it is not an immutable-storage guarantee. `sizeof(Vertex)` includes any padding chosen for the structure, so the later stride must use that same size.

The element-buffer upload similarly copies `indices.size()*sizeof(unsigned int)` bytes from `indices.data()` after binding `GL_ELEMENT_ARRAY_BUFFER`. Unlike the generic array-buffer binding, this element-buffer binding is stored in the currently bound VAO. The CPU vectors can later be destroyed after upload because the driver has its own buffer storage. This function does not check OpenGL error codes or validate that indices are within the vertex range, so correct input and a valid current graphics context are prerequisites.

20. Original Lines 276-288: Attribute Locations, Byte Offsets, and the Returned Mesh

The attribute-layout comment fixes the contract between uploaded `Vertex` records and shader inputs: location 0 is position, 1 is normal, and 2 is UV. `glVertexAttribPointer` does not copy one attribute at a time; it records how the GPU should find that attribute in the currently bound array buffer.

Position uses three `GL_FLOAT` components, normal also three, and UV two. `GL_FALSE` means OpenGL should not apply integer-to-normalized-value conversion. Each attribute has stride `sizeof(Vertex)`, so advancing to the next vertex advances one complete record. `offsetof(Vertex, pos)`, `offsetof(Vertex, normal)`, and `offsetof(Vertex, uv)` compute member byte offsets, preserving correctness if the type contains padding rather than assuming tightly packed offsets of 0, 12, and 24.

The `(void*)` casts encode byte offsets for the buffer-backed attribute API. They do not mean that OpenGL will dereference arbitrary CPU addresses while drawing. Each `glEnableVertexAttribArray` enables the corresponding attribute; defining its pointer alone would not enable array fetching. All these attributes are per-vertex by default because this function does not set instancing divisors.

`glBindVertexArray(0)` unbinds the newly configured VAO, reducing accidental subsequent edits to its state. It does not unbind every global buffer target or delete any object. `return m` passes the resulting handle record back to the primitive builder's caller. The closing brace finishes upload. Draw mode remains the default triangles because this function never changes it. Uploading a mesh also does not choose a shader, assign materials, or issue a draw call; those are separate responsibilities handled later.

Procedural Primitive Builders

21. Original Lines 290-314: createCube, Its Face Lambda, and Six Faces

The comment describes a cube with separate normals per face. `createCube()` creates empty vertex and index vectors, then defines a local lambda named `addFace`. A lambda is a small unnamed function stored in a variable. Its `[&]` capture gives it reference access to the surrounding vectors so its `push_back` calls modify the builder's data. The parameters are four corner positions and one shared face normal.

Inside the lambda, `base` records the current vertex count before appending. Four new vertices receive the same normal and the four UV corners $(0, 0)$, $(1, 0)$, $(1, 1)$, and $(0, 1)$. The six appended indices select triangles $(base, base+1, base+2)$ and $(base, base+2, base+3)$, splitting the face along the diagonal from its first to third corner. A triangle's index order determines its winding, which matters if face culling is enabled elsewhere. The lambda's closing `}`; finishes its body and local declaration.

Six calls supply faces at $Z=+0.5$, $Z=-0.5$, $X=-0.5$, $X=+0.5$, $Y=+0.5$, and $Y=-0.5$. Their normals are respectively $(0, 0, 1)$, $(0, 0, -1)$, $(-1, 0, 0)$, $(1, 0, 0)$, $(0, 1, 0)$, and $(0, -1, 0)$. Every coordinate magnitude is 0.5, so the cube is centered at the origin with side length one. The supplied corner orders give outward-facing triangles under the usual counterclockwise convention.

The cube has 24 vertex records, not just eight unique spatial corners, because a shared corner needs three different normals for three sharply separated faces. It has 36 indices and 12 triangles. This duplication produces a crisp box rather than a rounded-looking cube with averaged corner normals. `return uploadMesh(v, idx)` uploads those arrays and returns the GPU handle record; the final brace finishes the builder. Changing an object's apparent box dimensions happens through a later model scale, not by rebuilding this unit cube.

22. Original Lines 316-334: createCylinder and Smooth Side Vertices

`createCylinder(int slices = 24)` takes an optional circumferential segment count. Calling it without an argument uses 24. A default argument selects a value at the call site; it does not stop callers from passing another value. The function creates local vertex and index vectors, then sets radius $r=0.5$ and height $h=1$. The cylinder is aligned with Y and centered at the origin.

The body loop uses `i <= slices`, generating 25 angular samples at the default rather than 24. The first and final sample occupy the same seam direction but have different U coordinates. $\theta = i/slices * 2\pi$ covers a full revolution; explicit floating-point casts prevent integer division from collapsing most fractions to zero. $c=\cos(\theta)$ and $s=\sin(\theta)$ locate the circle direction. $norm=(c, 0, s)$ is the outward radial side normal, of unit length in ideal arithmetic.

At each angle, the function appends a lower vertex $(r*c, -0.5*h, r*s)$ and an upper vertex $(r*c, +0.5*h, r*s)$. Their UVs are $(u, 0)$ and $(u, 1)$, with $u=i/slices$. The result is a strip of vertical pairs, suitable for two triangles between neighboring pairs. Shared normals around the circumference allow interpolation to make the side look smooth despite its polygonal silhouette.

The duplicated seam supports UV values zero and one without forcing interpolation across a discontinuity. This is normal for textured cylinder construction even though the scene shader does not currently use its UV coordinates for surface color. The input is not validated: zero slices creates division by zero, and too few slices give a degenerate or very coarse object. Intended calls therefore need a sensible positive slice count. The body loop closes at line 334, but the function continues by generating its indices and separate caps.

23. Original Lines 336-354: Cylinder Side Indices and Top Cap

The side-index loop runs from zero to `slices-1`. $b=i*2$ is the lower vertex in the current angular pair. The upper current vertex is $b+1$; the lower and upper next vertices are $b+2$ and $b+3$. Triangles $(b, b+1, b+3)$ and $(b, b+3, b+2)$ fill that rectangular panel. With 24 slices, the side contributes 48 triangles and 144 indices.

The top-cap section starts by storing `topCenter=v.size()`, the future center vertex index. It appends $(0, +0.5*h, 0)$ with upward normal $(0, 1, 0)$ and UV $(0.5, 0.5)$. The rim loop again includes the endpoint, creating

`slices+1` cap rim vertices. Each lies at $(0.5 \cdot \cos(\theta), +0.5, 0.5 \cdot \sin(\theta))$ and receives the same upward normal as the center, not the side's radial normal.

Cap UVs map the circle into a unit square: `U` is $0.5 + 0.5 \cdot \cos(\theta)$ and `V` is $0.5 + 0.5 \cdot \sin(\theta)$. The `+0.5` moves the circle center to the square center, and the `0.5` factor fits its coordinates into zero through one. The cap uses its own rim records even where positions coincide with side vertices, allowing the hard normal transition between side and lid.

The top-index loop makes a triangle fan using the center, next rim vertex, then current rim vertex. That reversed rim order is deliberate: when seen from above, it produces an upward-facing cap. Each slice contributes one top triangle. The closing braces finish the rim and fan loops; no cap thickness or bevel is generated. This is a flat closed disk, not a domed pressure-vessel head. A later sphere primitive can be used for a dome in an assembled model.

24. Original Lines 355-369: Cylinder Bottom Cap and Final Counts

The bottom cap mirrors the top but lies at `Y=-0.5`. Its center is assigned the index `btmCenter`, position $(0, -0.5 \cdot h, 0)$, downward normal $(0, -1, 0)$, and center UV $(0.5, 0.5)$. The inclusive rim loop generates the same angular samples and circular UV mapping at the lower height.

Its triangles use the center, current rim, then next rim. This order is opposite the top fan because the outward-facing direction is now downward. Simply copying the top index order would make the bottom's geometric face orientation disagree with its assigned normal. The separate rim and center vertices keep the lower cap flat-shaded with its own normal.

For `s` slices, the body has $2 \cdot (s+1)$ vertices, and each cap has one center plus `s+1` rim vertices. Total vertices are therefore $4 \cdot s + 6$: 102 at the default 24. Total triangles are $2 \cdot s$ on the side plus `s` on each cap, or $4 \cdot s$: 96 by default. The index count is $12 \cdot s$, or 288. These counts include duplicated seams and duplicated side/cap positions, which are necessary for the chosen shading and UV layout.

`return uploadMesh(v, idx)` sends the entire closed primitive to the GPU, and the closing function brace ends construction. No dimensions are exposed beyond the fixed unit geometry and slice count; arbitrary radius and height are obtained later through scaling. Nonuniform scaling requires a correctly transformed normal, which the scene vertex shader supplies through an inverse-transpose matrix.

25. Original Lines 371-392: createSphere and Latitude-Longitude Vertices

`createSphere(int lats=16, int lons=24)` produces a radius-0.5 UV sphere. The two defaults mean 16 latitude bands and 24 longitude sectors, not 16 times 24 total vertices. Local arrays hold the generated records and indices.

The outer loop includes all latitude endpoints, from `i=0` to 16. Its angle $\theta = i / \text{lats} \cdot \pi$ spans zero at the north pole to π at the south pole. `sinT` is the horizontal circle-radius factor and `cosT` the vertical component. The inner loop includes `j=0` through 24, with $\phi = j / \text{lons} \cdot 2 \cdot \pi$, so it also duplicates a seam.

The normal is $(\sin(\theta) \cdot \cos(\phi), \cos(\theta), \sin(\theta) \cdot \sin(\phi))$. Squaring and summing its components yields one in ideal arithmetic, so this is a unit outward direction. Multiplying by 0.5 gives a point on a sphere of radius 0.5 centered at the origin. UV is $(j / \text{lons}, i / \text{lats})$: `U` moves around the sphere, `V` moves from pole to pole. The vertex append stores those three values together.

The two closing braces end the nested vertex loops. With defaults, there are $(16+1) \cdot (24+1) = 425$ records. At each pole, many longitude records coincide spatially, but their UV values differ. Such duplication permits a rectangular parameterization while creating some degenerate pole triangles in the later indexing. As with the cylinder, zero divisors or unsuitable negative counts are not checked here. The function expects valid positive subdivisions; it neither adaptively refines the sphere nor loads an existing model.

26. Original Lines 394-410: Sphere Cell Indices and Degenerate Pole Triangles

The indexing loops visit 16 latitude bands and 24 longitude cells per band. Because a complete vertex row contains `lons+1` records, `first=i*(lons+1)+j` addresses the current row and longitude. `second=first+lons+1` addresses the same longitude on the next latitude row.

The first triangle is (first, first+1, second) and the second is (second, first+1, second+1). Together they fill a latitude-longitude cell. The ordering gives outward orientation away from the poles for this position parameterization. Each cell always appends six indices; there is no branch to remove collapsed pole faces.

With defaults, the total is $16 * 24 * 2 = 768$ submitted triangles and $16 * 24 * 6 = 2304$ indices. One triangle in each cell adjoining each pole has coincident pole vertices in exact mathematics, so 48 of the submitted triangles are degenerate. The remaining 720 represent the actual sphere surface. Floating-point sine near pi may produce tiny coordinate differences at the south pole, but the intended shape still has that pole collapse.

The nested closing braces finish the index loops, and `uploadMesh` returns the sphere's GPU record. Smooth normal interpolation gives a round-looking surface, while the silhouette remains limited by the chosen mesh resolution. UV poles compress many longitudinal samples into one spatial point; this familiar distortion is a limitation of UV spheres rather than an OpenGL error. The shader cannot make the 24-sector silhouette arbitrarily smooth merely by smoothing lighting.

27. Original Lines 412-436: createWingBlade and the Tapered Four-Point Profile

The wing builder creates a slender primitive along positive X, from root $X=0$ to tip $X=1$. The comment gives approximate tip values of 0.25 chord and 0.02 thickness, but the actual expressions use **0.22 chord and 0.015 thickness**. The code, not those rounded comments, defines the mesh.

`spanSegs=8` yields nine cross-sections through an inclusive loop. $t=i/8$ is a normalized span coordinate and $x=t$. Chord is $\text{mix}(1, 0.22, t) = 1 - 0.78 * t$; thickness is $\text{mix}(0.08, 0.015, t) = 0.08 - 0.065 * t$. At the root, thickness is 0.08; at the tip it is 0.015. The primitive has straight linear taper, not a physically derived airfoil equation.

Each section contains four points: leading edge ($x, 0, -0.45 * \text{chord}$), top crest ($x, +0.5 * \text{thick}, -0.1 * \text{chord}$), trailing edge ($x, 0, +0.55 * \text{chord}$), and bottom crest ($x, -0.5 * \text{thick}, -0.1 * \text{chord}$). The chord extends 45 percent forward and 55 percent backward relative to $Z=0$. The crests lie near the leading portion, making a thin diamond-like cross-section rather than an anatomically accurate insect-wing membrane.

Assigned normals are the coordinate directions $(0, 0, -1)$, $(0, 1, 0)$, $(0, 0, 1)$, and $(0, -1, 0)$. Normalizing these already-unit vectors changes nothing. Their UVs are $(t, 0)$, $(t, 0.33)$, $(t, 0.66)$, and $(t, 1)$. These normals are artistic approximations and ignore taper-induced X components; they are not computed from the actual sloped faces. Thirty-six vertex records result. The loop closes at line 436, and the mesh still needs connectivity along its span.

28. Original Lines 438-449: Wing Connectivity, Wraparound, and Open Ends

For each of eight span intervals, $b1=i * 4$ addresses the current section and $b2=(i+1) * 4$ the next. The inner loop visits all four profile edges. $kNext=(k+1)\%4$ advances to the next point and wraps index 3 back to 0, closing the cross-section around the leading edge.

Each edge receives triangles $(b1+k, b2+k, b2+kNext)$ and $(b1+k, b2+kNext, b1+kNext)$. Across eight intervals and four edges, this produces 64 triangles and 192 indices. Closing the profile around each section does not close the root and tip: no end-cap triangles are added. The blade is therefore an open-ended tapered shell. Its integration into a hub can hide the root opening, but that is an assembly decision outside this builder.

There is also a distinction between assigned shading normals and winding. For the upper-leading panel, the index order gives a geometric normal generally opposite the intended outward upper-leading direction, while vertex normals are assigned outward-looking axis directions. Thus the index order and the artistic normals should not be assumed to agree. With face culling enabled, this matters for which side is visible; with culling disabled, it can still yield lighting that does not match the geometric face orientation. The function does not correct winding as the rock builder later does.

The inner and outer braces close the profile and span loops. The return uploads the blade, and the final brace finishes construction. Wing count, flapping phase, and aerodynamic banking are not implemented in this primitive; repeated transformed draws can turn one blade mesh into an eight-wing aircraft.

29. Original Lines 451-471: createDuneTerrain, Reservations, and Vertex Sampling

The terrain builder defaults to `gridW=140`, `gridH=140`, and `totalSize=700`. It creates vectors and reserves space for $(\text{gridW}+1) * (\text{gridH}+1)$ vertices and $\text{gridW} * \text{gridH} * 6$ indices. `reserve` increases capacity without creating those elements; subsequent `push_back` calls still populate the vectors. This avoids repeated reallocations during predictable construction.

`halfSize=350` and `step=700/140=5` define the default horizontal spacing. The Z loop runs from zero through `gridH`, and the X loop from zero through `gridW`. World coordinates are `worldX=-350+5*x` and `worldZ=-350+5*z`, covering -350 through +350 on both axes. These are generated directly as terrain coordinates; a later model matrix can still transform the whole mesh.

`worldY=getDuneHeight(worldX, worldZ)` includes the landing terrace. `norm=getDuneNormal(...)` calculates the finite-difference shading normal. Together, one vertex requires its own height query plus four height samples for the normal. Default construction therefore involves 19,881 direct height evaluations and 79,524 normal-related height evaluations, or 99,405 calls to `getDuneHeight`, apart from the terrace array's one-time initialization.

UV is $(\text{worldX} * 0.05, \text{worldZ} * 0.05)$, so one UV unit corresponds to 20 world units. Its default range is -17.5 to +17.5; UV coordinates need not stay in $[0, 1]$. The scene's sand pattern currently uses world positions rather than this UV. The vertex append stores all data, and the braces finish both sampling loops.

A subtle limitation is that both axes use a step derived only from `gridW`. If `gridH` differs from `gridW`, the Z span is $\text{gridH} * \text{totalSize} / \text{gridW}$, not necessarily `totalSize`, and its positive endpoint may not be `+halfSize`. The defaults are square and avoid that mismatch, but the function's parameters suggest more flexibility than its step calculation actually provides.

30. Original Lines 473-489: Terrain Triangles and Finite Rendered Extent

The cell loops use strict less-than conditions, so they visit 140 by 140 cells instead of the inclusive 141 by 141 vertex positions. `row1=z*(gridW+1)` and `row2=(z+1)*(gridW+1)` locate neighboring vertex rows. Each cell is split into triangles $(\text{row1}+x, \text{row2}+x, \text{row1}+x+1)$ and $(\text{row1}+x+1, \text{row2}+x, \text{row2}+x+1)$.

On a flat Y-up grid, the first triangle's Z-forward edge crossed with its X-forward edge points upward, so this index order matches upward-facing terrain. Both triangles share the diagonal between the next-row current-X vertex and the current-row next-X vertex. Shared vertices allow adjacent cells to meet without cracks when their transformation is the same.

Defaults produce $140 * 140 = 19,600$ cells, 39,200 triangles, 117,600 indices, and 19,881 vertex records. The upload returns one static mesh. The function does not regenerate vertices around the camera, create terrain chunks, or implement level of detail. The height query is mathematically continuous over the horizontal plane, but the rendered mesh is a **finite sampled patch** covering a 700-unit square.

Within each triangle, rasterization interpolates its planar geometry. It does not evaluate the CPU sine height function at every interior pixel. Collision/height queries at intermediate coordinates can therefore disagree slightly with the triangle surface, particularly near sharper ridges or terrace boundaries. Shader ripples later improve apparent detail without adding geometric vertices. The two loop-closing braces, `return`, and function-closing brace finish the terrain builder and do not change any simulation state beyond GPU-object creation.

31. Original Lines 491-501: createQuad and the Particle Unit Square

The quad comment identifies its billboard use. `createQuad()` initializes four Vertex records directly: bottom-left $(-0.5, -0.5, 0)$, bottom-right $(0.5, -0.5, 0)$, top-right $(0.5, 0.5, 0)$, and top-left $(-0.5, 0.5, 0)$. All have normal $(0, 0, 1)$. Their UVs are the corresponding corners $(0, 0)$, $(1, 0)$, $(1, 1)$, and $(0, 1)$.

This is a unit square in the local XY plane, centered on the origin. The initializer's braces group the vector, each vertex, and each member's coordinate components. They are data initialization, not nested loops. Indices $\{0, 1, 2, 0, 2, 3\}$ make two counterclockwise triangles facing positive Z.

The return uploads four vertices and six indices. The primitive is not inherently camera-facing; **billboarding is implemented by the particle vertex shader**, which combines local X/Y with camera-right and camera-up vectors. The stored normal is unused by that shader, which does not declare location 1. Keeping the common Vertex format lets this quad use the generic upload routine anyway.

The particle fragment shader will discard fragments outside a UV-space circle, so a square mesh can visually appear as a soft circular dust patch. The geometry itself remains two square-covering triangles. This separation between simple geometry and shaped opacity is an efficient rendering technique, not the creation of a true circular polygon or a volumetric cloud.

32. Original Lines 503-517: createRing and a Thin Torus

`createRing()` creates a torus: a circular tube swept around a larger circle. The compact nested loop has $i=0..80$ around the major circle and $j=0..8$ around the tube cross-section, both inclusive. Angles are $a=i*2\pi/80$ and $b=j*2\pi/8$.

The normal is $(\cos(a)*\cos(b), \sin(b), \sin(a)*\cos(b))$, of unit length in exact arithmetic. The major-circle centerline is $(\cos(a), 0, \sin(a))$, with radius one in the XZ plane. Adding $0.025*n$ supplies tube radius 0.025. Consequently the ring's outer horizontal radius is 1.025, its inner radius 0.975, and its vertical range is -0.025 to +0.025. UV is $(i/80, j/8)$, with duplicated endpoint records for both seams.

The second nested loop visits 80 by 8 cells. $a=i*9+j$ is an index here, reusing the earlier name in a separate scope; it is no longer an angle. $b=a+9$ addresses the next major-circle row because each row has nine tube samples. `indices.insert(indices.end(), {...})` appends six indices at once: two triangles $(a, a+1, b)$ and $(b, a+1, b+1)$. This is functionally similar to six `push_back` calls.

The mesh has $81*9=729$ vertices, 1,280 triangles, and 3,840 indices. The eight-sided tube gives it a polygonal cross-section despite smooth normals. The return uploads it and closes the builder. The shape is not a flat annulus: it has a thin three-dimensional circular tube, which can be scaled or placed as a visual marker later.

33. Original Lines 519-526: createErodedRock and the Point-Generating Lambda

The rock builder creates empty arrays and a captureless lambda point. Its `[]` capture means it uses only its arguments and accessible global/static functions, not local builder variables. Parameters `lat` and `lon` are integer grid indices. Angle $a=lat*\pi/8$ follows eight latitude bands, while $b=lon*2\pi/13$ follows thirteen longitude sectors.

The erosion factor is $0.83 + 0.13*\sin(7.1*lon+2.3*lat) + 0.08*\cos(5.4*lat)$. Independent bounds place it between 0.62 and 1.04. This name describes an artistic irregularity; there is no iterative erosion process, water simulation, or random seed. The perturbation is deterministic and depends on integer indices rather than on a continuous world-space noise field.

The returned point is $0.5*(\sin(a)*\cos(b)*erosion, \cos(a), \sin(a)*\sin(b)*erosion)$. The erosion factor changes X/Z radius but not Y. Y still ranges approximately -0.5 to +0.5, while maximum horizontal radius is bounded by 0.52. The result resembles a vertically parameterized irregular rock rather than a uniformly perturbed sphere.

There is a seam limitation: `point(lat, 0)` and `point(lat, 13)` have matching angular directions but generally **different erosion factors**, because the sine expression in `lon` is not periodic over thirteen samples. The longitude strip closes in angle without necessarily closing in position, leaving a geometric mismatch along the seam away from the poles. The lambda closes at line 526; later code consumes its points to create flat-shaded triangles and handles degenerate pole faces.

34. Original Lines 527-541: Rock Triangle Lambda, Winding Repair, and Flat Shading

The local `tri` lambda captures the vectors by reference and accepts three positions by value. `cross(b-a, c-a)` computes an area-weighted triangle normal. Its length equals twice the triangle area. If that length is below 0.00001, the lambda returns early, avoiding normalization of an almost-zero vector and excluding collapsed pole triangles.

The orientation test is `dot(n, a+b+c) < 0`. Since the geometry is centered around the origin, the sum of its three vertex positions points roughly toward the triangle's exterior location. A negative dot suggests that its normal points

inward. The branch swaps B and C to reverse winding and negates n to match the new order. This is an origin-relative heuristic appropriate to the intended roughly convex rock, not a universal normal repair for arbitrary concave meshes.

After normalization, `start` records the vertex count using an explicit `static_cast<unsigned int>`. Three vertices are appended with the same normal and UVs $(0, 0)$, $(1, 0)$, $(1, 1)$, followed by indices `start`, `start+1`, and `start+2`. Each triangle gets separate vertex records, even where corners coincide with another face. That duplication prevents interpolation across different face normals and creates a deliberately faceted appearance.

The nested loops visit eight latitude bands and thirteen sectors. Each cell attempts two triangles using the point `lambda`. There are 208 attempts; in ideal geometry, 26 pole-degenerate triangles are skipped, leaving 182 nondegenerate triangles, 546 independent vertex records, and 546 indices. The threshold also rejects tiny numerical pole artifacts. There is no global UV unwrap: every triangle gets the same small UV pattern. The return uploads the resulting rock. Winding repair does not weld its seam or turn this artistic perturbation into a physically eroded geological model.

35. Original Lines 543-557: Shared Mesh Handles and Packed Particle Instances

The mesh-assets comment introduces eight global Mesh records: `g_meshCube`, `g_meshCylinder`, `g_meshSphere`, `g_meshWing`, `g_meshTerrain`, `g_meshQuad`, `g_meshRing`, and `g_meshRock`. Their names connect them to the builders just explained. Each begins with the structure's zero handles, zero index count, and triangle draw mode. Merely declaring them does not invoke the corresponding builder; later initialization must assign uploaded meshes.

`g_particleInstanceVB0 = 0` stores the future buffer handle for per-particle instance data. `ParticleInstance` is a compact record with two `glm::vec4` members. `posSize` packs position in X/Y/Z and size in W. `colorAlpha` packs RGB color and alpha in W. This packing matches particle shader inputs at locations 3 and 4. It is distinct from `SandParticle`: simulation stores velocity and lifetime, while the instance record stores only what drawing needs.

`g_particleInstances` is an initially empty vector of those packed draw records. Later code can rebuild it from the simulation pool and upload many instances for one instanced draw. These lines do not establish attribute divisors or perform the draw; declaring attributes in a shader does not automatically make a buffer advance once per instance. Proper VAO/buffer configuration must be supplied elsewhere.

The one-line structure's braces and semicolon define its member grouping. The storage format assumes that the upload and attribute layout agree on stride and offsets; using `sizeof` and `offsetof` is preferable to assuming a particular GLM packing configuration. Separating simulation and rendering records avoids sending unused velocity/lifetime values to the GPU for this simple billboard shader.

Surface Shader Interface and Vertex Processing

36. Original Lines 558-580: SCENE_VERT, Attributes, Uniforms, and Varyings

Lines 558-560 label shader data. The surface-shader comment names intended lighting features; the vertex shader itself handles geometry and passes data to a later fragment shader. `const char* SCENE_VERT = R"(` starts a C++ raw string. Its contents are GLSL source, not directly executed C++. Raw-string syntax lets embedded newlines and quotation marks appear without ordinary escape sequences. A later compiler call sends this text to OpenGL.

`#version 330` core requests GLSL 3.30 in the core language profile. Attributes at locations 0, 1, and 2 are `aPos`, `aNorm`, and `aUV`, matching the generic mesh upload. These are per-vertex values. **Uniforms** are values set by C++ that remain constant for a draw rather than vary for each vertex:

- `model` maps mesh-local positions into world coordinates. It also determines the normal transformation.
- `view` maps world coordinates into camera coordinates.
- `projection` maps camera coordinates into clip coordinates for perspective or another chosen projection.
- `lightSpaceMatrix` maps world coordinates into the sun/shadow camera's clip space.
- `wormCenter` supplies the world-space center for terrain depression; only its X/Z components are used here.

- `collapse` supplies the scalar amount of depression. This range declares it but supplies no default or runtime maximum.

- `isSand` selects a material/geometry mode. Value 1 enables terrain depression; other values do not in this shader.

Outputs `FragPos`, `Normal`, `TexCoord`, and `FragPosLight` carry world position, transformed normal, UV, and light clip-space position to the fragment stage. Default smooth interpolation blends vertex outputs across triangles, normally with perspective correction. Passing a vector named `Normal` does not automatically keep it unit length after interpolation; the fragment shader normalizes it again. The light output is a four-component homogeneous coordinate and must later be divided by `W` before texture-coordinate comparison.

37. Original Lines 582-594: Scene Vertex `main`, Collapse, and Coordinate Transforms

GLSL's `main` is the entry point executed for each vertex. `worldPos=model*vec4(aPos,1)` places a local vertex in world space. The `if(isSand==1)` branch limits terrain collapse to the designated sand mode.

`d=length(worldPos.xz-wormCenter.xz)` is horizontal radial distance from the worm; `Y` differences do not matter.

The depression is `collapse*(1-smoothstep(5,48,d))*13`, subtracted from `Y`. Within five units, the radial weight is one; beyond 48 it is zero. In the transition band, a smooth cubic reduces the displacement. If `collapse=1`, the central depression is 13 units; if `collapse=0.5`, it is 6.5. At distance 26.5, halfway between the two radii, the weight is 0.5. Nothing here clamps `collapse`, so a negative value would raise terrain and a value above one would deepen it beyond thirteen units.

`FragPos=worldPos.xyz` passes the displaced world position.

`Normal=mat3(transpose(inverse(model)))*aNorm` applies the inverse-transpose normal matrix and discards translation through conversion to `mat3`. The inverse transpose corrects orientation under nonuniform scaling. It assumes `model` is invertible; a zero scale can make inversion undefined. The fragment shader later renormalizes the result.

Importantly, the normal does **not** incorporate the derivative of the collapse deformation. The vertex height moves but its supplied terrain normal remains based on the undepressed CPU heightfield. CPU `getDuneHeight` queries also remain unchanged. This can cause lighting and object/particle placement to disagree with the visible crater. The deformation is sampled only at existing terrain vertices, so its smooth radial formula is represented by a finite triangle mesh.

`TexCoord=aUV` passes UV unchanged. `FragPosLight=lightSpaceMatrix*worldPos` uses the displaced position so shadows refer to the same geometry. `gl_Position=projection*view*worldPos` supplies the camera's clip-space position, with matrices applied right to left. The closing GLSL brace ends `main; )`; closes the raw string and its C++ declaration, not another rendering pass.

38. Original Lines 596-620: SCENE_FRAG Inputs and Every Surface Uniform

`SCENE_FRAG` begins a second GLSL raw string at version 330 core. Inputs `FragPos`, `Normal`, `TexCoord`, and `FragPosLight` match the vertex outputs by name and type. `FragColor` is the four-component color result. Although UV is declared, the visible surface calculations below do not use `TexCoord`; a compiler may optimize that varying and its input attribute away for this program.

The material uniforms are `objectColor`, the RGB base/diffuse color; `specularColor`, an RGB multiplier for highlights; `shininess`, the specular exponent; `emissiveColor`, an added self-lit RGB term; and `isSand`, the integer mode selector. Value zero uses ordinary material behavior. Value one receives sand ripples, wrap lighting, and the vertex collapse. Value two receives rock-like grain and layering but no sand collapse or wrap branch. Despite its name, `isSand` is therefore more than a Boolean.

Lighting uniforms are `lightDir`, documented as the direction **toward** the sun; `sunColor`, the RGB direct-light multiplier; `ambientColor`, the RGB ambient-light multiplier; and `viewPos`, the world-space camera position.

Directional light uses one common direction for the entire scene, with no distance attenuation from a sun position. The fragment shader normalizes `lightDir` for its local lighting vector, but the shadow bias later uses the uniform directly, so the caller should honor the normalized-direction contract.

`sampler2D shadowMap` identifies a texture unit from which ordinary depth samples are read. It is not a `sampler2DShadow`, so the shader performs the depth comparison itself. `fogColor` is the RGB endpoint for distant haze, and `fogDensity` controls the exponential-squared distance response. No initial values are assigned in this string; C++ must supply intended scene values. The fog comment describes an artistic warm-desert effect, not a measured atmospheric scattering model. The shader has no uniform for a diffuse texture, roughness map, metalness, point lights, or normal-map image.

Surface Shadow Filtering

39. Original Lines 621-635: `calcShadow`, Projection, Receiver Slope, and Bias

`calcShadow(vec4 fragLight, vec3 norm)` returns a scalar occlusion fraction. It first divides light clip-space XYZ by W to obtain normalized device coordinates. Multiplying by 0.5 and adding 0.5 changes the usual $[-1, 1]$ coordinate range into $[0, 1]$, suitable for texture coordinates and depth comparison. The code assumes a valid nonzero W; there is no guard against division by zero.

`dFdx(proj)` and `dFdy(proj)` estimate how projected coordinates vary over neighboring screen fragments. Here `dx` and `dy` are not world-space terrain samples: they are GPU fragment derivatives. Their X/Y components describe changes in shadow-texture coordinates and their Z components describe changes in receiver depth. The determinant `dx.x*dy.y - dx.y*dy.x` measures whether those two projected screen directions define an invertible two-dimensional mapping.

The desired receiver-depth slope (`sx, sy`) satisfies $dx.z = sx * dx.x + sy * dx.y$ and $dy.z = sx * dy.x + sy * dy.y$. Solving these two equations gives exactly the code's numerator pair divided by the determinant. The initial slope is $(0, 0)$. Only if `abs(determinant) > 0.000000001` does the shader apply the division; near-degenerate mappings retain zero correction rather than amplify numerical noise through an unstable inverse.

The following one-line conditional returns zero shadow if Z is below zero or above one, or if either texture coordinate is below zero or above one. `lessThan` and `greaterThan` return Boolean component vectors; any tests whether at least one component qualifies. A fragment outside the light's map is treated as unshadowed rather than clamped into the map. Equal endpoints are accepted. Derivatives are computed before this early return.

Bias is `max(0.0035*(1-dot(norm, lightDir)), 0.0008)`. A surface facing the sun receives the minimum 0.0008; perpendicular directions give 0.0035; perfectly opposite directions would give 0.007 if both vectors are unit length. Bias shifts comparison toward "lit" to reduce self-shadow acne, at the risk of detached or weakened shadows. These are **normalized depth units**, not world distances. `shadow=0` initializes the accumulator. `texelSize=1/textureSize(shadowMap, 0)` derives one base-level texel step; for a 2048-square texture, each component is $1/2048 = 0.00048828125$.

40. Original Lines 636-645: The Exact 5-by-5 PCF Loop

The comment specifies a 5-by-5 filter. The outer loop uses integer X offsets -2,-1,0,1,2, and the inner loop uses the same Y offsets. There are exactly 25 iterations, not a 3-by-3 filter or an adaptive sample count. Each integer pair multiplied by `texelSize` becomes a shadow-texture offset, spanning two texels in either direction from the receiver.

`texture(shadowMap, proj.xy+offset).r` reads the stored depth sample's first component. The texture is configured later with nearest-neighbor filtering, so each fetch selects a depth texel instead of averaging neighboring depths. The shader does the comparison manually: the sample counts as shadowed when `proj.z + dot(depthSlope, offset) - bias > pcfDepth`.

The dot product estimates how the receiver's own depth changes between the central projected coordinate and this tap. Without it, a sloping surface might compare every tap against one center depth and generate striped self-shadow artifacts at low sun angles. Subtracting bias makes the test less likely to label the receiver as behind itself. The ternary adds 1 for a failed light-visibility test and 0 otherwise. Strict greater-than means equal biased depth is treated as lit.

The two loop braces close the 25-sample traversal. `return shadow/25` gives values from zero to one in increments of 0.04. Ten occluded taps return 0.4; all 25 return one. This is **percentage-closer filtering**: it averages comparison results, not raw depths, to soften shadow edges. It does not estimate a real sun's angular size, sample a physical

penumbra, or provide contact-hardening soft shadows. Its fixed texel footprint also changes apparent world-space softness if the light's covered region changes.

The earlier bounds test checks the center only. Edge taps can extend beyond the texture, where the later white border-depth setting supplies depth one. Such taps generally count as lit and soften shadows near map boundaries. The final brace closes `calcShadow`; no color has yet been produced.

Surface Material and Lighting Calculations

41. Original Lines 647-658: Fragment Directions and Rock-Mode Color Variation

Surface fragment main begins by normalizing `Normal`, the interpolated world-space normal, to obtain `N`. `L=normalize(lightDir)` points toward the sun. `V=normalize(viewPos-FragPos)` points from the surface toward the camera. `H=normalize(L+V)` is the halfway direction between light and viewer, used by Blinn-Phong highlights. If the inputs yield a zero vector, such as exact opposing `L` and `V`, normalization is not guarded; normal operation assumes useful scene directions.

`baseCol=objectColor` starts with the material's RGB color. When `isSand==2`, the shader creates rock-style variation. `grain=fRACT(sin(dot(FragPos,(12.3,42.8,27.1)))*43758.5453)` reduces a world-position-dependent sine value to a fractional part. `fRACT(x)=x-floor(x)`, so the result is in $[0, 1]$ even for negative inputs. These constants are a common inexpensive hash-like visual pattern, not a rigorous random generator, and floating-point implementation differences can affect its precise appearance.

`layers=sin(5*FragPos.y + sin(0.8*FragPos.x))` creates bands chiefly controlled by height, with an X-dependent phase wobble. The nested sine shifts those layers rather than modifying actual geometry. At fixed X, the vertical repeat interval is $2\pi/5$, approximately 1.2566 units. The X phase wobble repeats every $2\pi/0.8$, approximately 7.854 units.

The color is multiplied by $0.88+0.12*layers+0.07*grain$. Its theoretical range is from 0.76 to just under 1.07. Thus this mode mostly darkens the supplied color but can slightly brighten it. It does not alter normals, shininess, or shadow depth, and it is not a texture image. The branch closes at line 658. Ordinary mode zero and sand mode one skip this rock variation entirely.

42. Original Lines 660-679: Sand Ripples, Slope Tint, Distance Fade, and Sparkles

The sand branch runs only for `isSand==1`. `ripple1=0.5*sin(2.2*x+1.4*z)+0.5` and `ripple2=0.5*sin(0.8*x-1.9*z)+0.5` create two wave patterns remapped into $[0, 1]$. Their 50-percent mix is their arithmetic average. Their perpendicular wavelengths are approximately 2.410 and 3.048 world units. The comment mentions wind alignment, but these numerical directions are hard-coded; they do not read the CPU `WIND_DIR` constant or adapt if wind changes.

`slope=clamp(dot(N,(0,1,0)),0,1)` measures upward orientation. The color mix between $0.82*baseCol$ and $1.15*baseCol$ is equivalent to multiplying by $0.82+0.33*slope$. Horizontal upward ground is brightest; steep or downward-facing orientations receive the darker factor. This is not a direct crest-versus-valley detector. A flat valley and a flat crest can both have upward normals and receive the same multiplier.

The fade is `1-smoothstep(25,120,length(viewPos-FragPos))`. Ripples and sparkle retain full strength within 25 units and vanish at 120 units or beyond. At 72.5 units, fade is 0.5. The color addition $(0.035,0.02,0.008)*(ripple-0.5)*fade$ shifts warm tint around zero, with component bounds of plus/minus 0.0175, 0.01, and 0.004 at full fade.

The normal is perturbed by $(0.055*\cos(q),0,0.035*\cos(q))*fade$, where $q=2.2*x+1.4*z$, then renormalized. This uses only the first ripple's phase and no Y perturbation. Its maximum added-vector magnitude is about 0.06519. It is a small artistic bump approximation, not the derivative of a displaced sand surface. Geometry and CPU heights stay unchanged. The split source lines 672-673 form one expression, not two separate updates.

Sparkle is `pow(max(dot(N,H),0),120)`, a narrow halfway-direction highlight. A second world-XZ hash uses coefficients (12.9898, 78.233) and the same large sine multiplier. Only `noise>0.88` adds

$(0.35, 0.3, 0.22) * \text{sparkle} * \text{fade}$ to base color. Roughly twelve percent of a well-distributed hash field meets that threshold, but it is not an exact particle count or probabilistic guarantee. Because this is added to base color before all lighting, it can influence ambient lighting too; "under direct sun" is an artistic description rather than an explicit sunlight-only gate. The closing brace ends sand-specific processing.

43. Original Lines 681-697: Ambient, Wrapped Diffuse, Specular, and Shadow Combination

Ambient lighting is the componentwise product $\text{ambientColor} * \text{baseCol}$. It is a constant-direction-independent approximation to environmental bounce light, not calculated interreflection or ambient occlusion. It remains present in full shadow because the later shadow multiplier does not affect this term.

$\text{NdotL} = \text{dot}(\text{N}, \text{L})$ measures sun-facing orientation. Ordinary materials and rock mode use $\text{diff} = \max(\text{NdotL}, 0)$, Lambert-style diffuse intensity. Sand instead uses $\max((\text{NdotL} + 0.35) / 1.35, 0)$. At $\text{NdotL} = 1$, the result is one; at zero it is about 0.25926; at -0.35 it becomes zero. Slightly sun-away surfaces therefore retain diffuse contribution, producing a soft wrapped appearance. This differs from a canonical $(0.5 * \text{NdotL} + 0.5)^2$ half-Lambert equation despite the comment's shorthand.

$\text{diffuse} = \text{diff} * \text{sunColor} * \text{baseCol}$ combines scalar illumination with colored sunlight and material color. The products of two RGB vectors are componentwise. Specular uses $\text{spec} = \text{pow}(\max(\text{dot}(\text{N}, \text{H}), 0), \text{shininess})$ and $\text{specular} = \text{spec} * \text{specularColor} * \text{sunColor}$. Larger positive exponents narrow highlights. For the default exponent 32, a halfway dot of 0.9 gives about 0.03434, while 0.99 gives about 0.72498. Material defaults are declared later; individual models can supply other exponents.

$\text{shadow} = \text{calcShadow}(\text{FragPosLight}, \text{N})$ uses the possibly ripple-perturbed normal for bias while receiver-plane slope comes from the projected position derivatives.

$\text{litColor} = \text{ambient} + (1 - \text{shadow}) * (\text{diffuse} + \text{specular}) + \text{emissiveColor}$ applies one visibility factor to both direct-light terms. A shadow of 0.4 retains 60 percent of diffuse and specular; a full shadow removes those terms but not ambient or emission.

The specular term is not explicitly gated on $\text{NdotL} > 0$, so a suitably oriented halfway vector can produce a highlight even when the light is behind the normal. emissiveColor brightens this fragment but does not cast light onto surrounding objects. There is no energy-conserving material model, multiple-scattering calculation, or transparency here. Comments separating the terms are explanatory labels, not extra execution.

44. Original Lines 698-706: Exponential-Squared Fog, Tone Mapping, and Opaque Output

$\text{dist} = \text{length}(\text{viewPos} - \text{FragPos})$ is three-dimensional camera-to-fragment distance, not just ground-plane distance or projected depth. Fog weight is $f = 1 - \exp(-(\text{dist} * \text{fogDensity})^2)$, clamped to $[0, 1]$. If the product of distance and density is 0.5, f is about 0.22120; at one it is about 0.63212; at two it is about 0.98168. The clear-image contribution is $1 - f = \exp(-(\text{dist} * \text{density})^2)$.

Density zero disables this fog for finite distances. Because density is squared as part of the product, a negative value would produce the same weight as its positive magnitude; the shader does not validate that a physically sensible nonnegative value was supplied. The clamp limits rounding or unusual results but is not a substitute for valid uniform data.

Before fog, each color channel is mapped as $\text{mapped} = (\text{lit} / (\text{lit} + 0.8))^{(1/1.8)}$. The rational fraction compresses positive bright values toward one, and the exponent is approximately 0.55556. For lit values 0, 0.8, and 1.6, the pre-exponent fractions are 0, 0.5, and 2/3. After the exponent, the latter two are approximately 0.68040 and 0.79833. This is an artistic tone/gamma-like transform, not a specified standard sRGB conversion or an HDR framebuffer guarantee.

The expression assumes nonnegative useful lighting values. A negative color can produce a negative fractional-power input or an unsuitable denominator; no explicit nonnegative clamp is present. $\text{mix}(\text{mapped}, \text{fogColor}, \text{fogFactor})$ then interpolates toward the supplied fog color. Fog color is mixed **after** the surface tone mapping and is not passed through that same expression in this shader.

`FragColor=vec4(...,1)` writes alpha one, making every surviving surface fragment opaque. Dark canopy colors therefore do not imply transparent glass. The GLSL brace closes `main`, and the raw-string terminator closes the C++ fragment-source declaration. Depth testing and blending state remain responsibilities of the draw pipeline outside this string.

Shadow and Particle Shader Programs

45. Original Lines 708-727: SHADOW_VERT, Matching Collapse, and Empty Fragment `main`

The shadow-pass comment introduces `SHADOW_VERT`, another GLSL 330 core raw string. It needs only position at attribute location zero. Its uniforms are `lightSpaceMatrix` for light clip coordinates, `model` for local-to-world placement, `wormCenter` for collapse center, `collapse` for displacement amount, and `isSand` for mode selection. It does not need UVs, normal attributes, material color, or camera matrices because it is constructing a depth map rather than a shaded image.

The vertex `main` starts with `p=model*vec4(aPos,1)`. The one-line sand conditional subtracts exactly the same `collapse*(1-smoothstep(5,48,length(p.xz-wormCenter.xz)))*13` depression as the scene vertex shader. Matching these deformations is essential: if the shadow pass rendered undeformed terrain while the visible pass rendered a crater, stored depths would disagree with visible receivers and casters.

`gl_Position=lightSpaceMatrix*p` projects into the light camera. The vertex function and its raw string then close. `SHADOW_FRAG` starts another version-330 string with `void main(){}`. The body is deliberately empty: no color output is required for a depth-only framebuffer. Rasterization and the fixed depth pipeline can still update its depth attachment using interpolated projected depth, subject to the OpenGL depth-state configuration established elsewhere.

An empty fragment shader is not the same as discarding all fragments. It simply omits a color computation. This shader does not explicitly write `gl_FragDepth`, pack depth into RGB, or store linear world-space distance. The framebuffer uses an actual depth texture, and the resulting values follow the chosen projection's depth mapping. The final string terminator and blank line end this pair of shader declarations, not the execution of a shadow frame.

46. Original Lines 728-750: PARTICLE_VERT and Instanced Camera-Facing Geometry

The particle comment calls these soft billboards. `PARTICLE_VERT` uses GLSL 330 core. Location zero supplies quad position; location two supplies UV. Location three supplies `instancePosSize`, whose XYZ are the particle center and W is size. Location four supplies `instanceColorAlpha`, whose RGB are color and W is opacity. These names match the earlier packed `ParticleInstance` record concept, though buffer association and per-instance divisors are established outside this range.

Uniforms `view` and `projection` are the camera transforms. `camRight` and `camUp` are world-space basis directions for the billboard plane. The caller should supply appropriately normalized, perpendicular directions if it wants a square of the requested size. Otherwise the vectors themselves can stretch, skew, or rotate the sprite. There is no per-particle model matrix, normal, or lighting direction in this shader.

Outputs `TexCoord` and `ColorAlpha` pass UV and packed color to the fragment stage. `main` first copies those values, then computes `worldPos=center+camRight*(aPos.x*size)+camUp*(aPos.y*size)`. For the unit quad, local X/Y span -0.5 to +0.5, so the full billboard width and height equal `size` when the basis is orthonormal. Local Z is ignored. Every vertex is built directly around the particle center rather than rotating an already placed mesh.

`gl_Position=projection*view*vec4(worldPos,1)` projects the billboard. The function and raw-string declaration close. With proper instancing setup, many particles share one quad mesh and this program while fetching different packed centers and colors. This shader alone does not sort translucent sprites, determine lifetime fade, implement world collisions, or sample a texture. "Soft" appearance comes from the next fragment shader's opacity profile, not from soft intersection against scene depth.

47. Original Lines 752-765: PARTICLE_FRAG, Circular Discard, and Opacity Falloff

The particle fragment string declares GLSL 330 core, input `TexCoord`, output `FragColor`, and input `ColorAlpha`. There are no uniforms in this fragment stage. The interpolated UV square is used as a mathematical opacity mask rather than coordinates into a sprite-image sampler.

`dist=length(TexCoord-vec2(0.5))` measures UV-space distance from the square center $(0.5, 0.5)$. The scalar constructor `vec2(0.5)` sets both components to 0.5. `if(dist>0.5) discard` removes fragments outside the inscribed circle; a corner has distance $\sqrt{0.5^2+0.5^2}$, about 0.7071, and is discarded. An exact point at radius 0.5 is not discarded, though its computed alpha becomes zero.

`soft=1-smoothstep(0,0.5,dist)` makes opacity one at the center and zero at the circle edge. At radius 0.25, the normalized smoothstep parameter is 0.5, so `soft` is 0.5. The output is

`vec4(ColorAlpha.rgb, soft*ColorAlpha.a)`: RGB is unchanged, while alpha falls smoothly to the boundary. This is ordinary, non-premultiplied color output because RGB is not multiplied by the resulting alpha.

The softness is not a Gaussian density profile, a volumetric integration, or depth-based soft-particle fading. Proper blending state must combine this alpha with the existing image, and appropriate depth testing/depth-write policy must prevent unwanted occlusion. Those states are not declared here. Unsorted overlapping translucent sprites can still exhibit order artifacts. Closing `main` and the raw string completes the shader source without issuing a draw.

Procedural Sky

48. Original Lines 767-780: SKY_VERT and Reconstructing World-Space Rays

The sky comment introduces a procedural clear desert sky rather than a cubemap texture. The vertex source declares GLSL 330 core, position at location zero, output `RayDir`, and uniform `invViewProj`. The uniform is the inverse of the camera's combined view-projection transform, conventionally `inverse(projection*view)`; the CPU must calculate and supply it.

In `main`, `farPoint=invViewProj*vec4(aPos.xy,1,1)` transforms a clip-space point at far-plane normalized $Z=+1$. `nearPoint=invViewProj*vec4(aPos.xy,-1,1)` transforms the matching near-plane point. Their XYZ components are divided by their own W values to recover world-space positions. Subtracting near from far gives a world-space ray direction through that screen coordinate. Removing the two points also cancels camera translation, so sky direction depends on orientation rather than absolute camera location.

The code assumes valid invertible camera matrices and nonzero resulting W components. An infinite-far projection would require careful treatment of the far homogeneous point; this shader does not guard for $W=0$. `RayDir` is not normalized yet; the fragment shader does that after interpolation.

`gl_Position=vec4(aPos.xy,0.9999,1)` places the fullscreen geometry close to the far depth boundary. Under the default OpenGL normalized-depth mapping, 0.9999 corresponds to depth approximately 0.99995. The input Z is ignored. This positioning helps a background sky coexist with scene depth, but actual results still depend on depth state and draw order outside these lines.

The later setup supplies three vertices, so this is a **fullscreen triangle**, not a geometric skybox or fullscreen quad. Its interpolation supplies a direction at each covered fragment. The brace and string terminator finish the source declaration.

49. Original Lines 782-800: SKY_FRAG and the Blue-Gold Elevation Gradient

The sky fragment source declares version 330, input `RayDir`, output `FragColor`, and uniforms `lightDir` and `sunColor`. Here the same conceptual sun direction locates the visible sun, while the sun color determines its additive RGB contribution. There are no cloud textures, cubemap samplers, fog-density uniform, or time-dependent noise inputs.

`rd=normalize(RayDir)` converts the reconstructed vector into a unit viewing direction. The three constant colors are `horizonDust=(0.90,0.74,0.47)`, a warm yellow-brown haze; `lowBlue=(0.48,0.69,0.88)`, a pale lower-sky blue; and `zenithBlue=(0.10,0.34,0.72)`, a deeper overhead blue. RGB values are numerical artistic choices, not samples from a physical atmospheric model.

`elevation=clamp(rd.y, 0, 1)` takes the vertical component of the ray. Since `rd` is unit length, this equals the sine of elevation angle above the horizontal, not the angle itself. Directions at or below the horizon are clamped to zero and receive the same initial warm haze color rather than an independently modeled lower hemisphere.

The first mix uses `smoothstep(0, 0.13, elevation)` to blend haze into low blue near the horizon. An elevation component of 0.13 corresponds to an angle of approximately $\text{asin}(0.13) = 7.47$ degrees. The second mix blends that result toward zenith blue with `elevation^0.65`. Because this exponent is below one, the weight grows comparatively quickly at low positive elevations. At component 0.5, the weight is about 0.63728; at one it is one, giving exact zenith blue before sun addition.

The two blends are sequential, so the final low-sky color is not merely a piecewise selection among three fixed values. The comment explicitly notes the absence of cloud noise, which matches the actual calculations. Line 800 is a blank separating gradient construction from the sun terms.

50. Original Lines 801-810: Sun Disk, Corona, Haze, and Untonemapped Sky Output

`sunDot=max(dot(rd, normalize(lightDir)), 0)` is the cosine of the angle to the sun, clipped at zero for the opposite hemisphere. Both participating directions are normalized here. The disk uses `smoothstep(cos(radians(0.80)), cos(radians(0.58)), sunDot)*1.9`. The `radians` calls convert degrees to the units expected by `cos`.

Cosine decreases as angle increases over this small range, so the first threshold, at 0.80 degrees, is smaller than the second, at 0.58 degrees. The `smoothstep` therefore transitions from zero beyond the outer angular radius toward full 1.9 strength inside the inner radius. The inner disk diameter is 1.16 degrees; the outer soft boundary diameter is 1.60 degrees. These are chosen visual sizes, not an inferred physical size from a sun distance and radius.

`sunCorona=pow(sunDot, 180)*0.30` creates a concentrated halo around the same direction.

`sunHaze=pow(sunDot, 12)*0.10` creates a much broader, weaker glow. At exact alignment, the three coefficients add to $1.9+0.3+0.1=2.3$. `finalSky=skyBase+(sunDisk+sunCorona+sunHaze)*sunColor` adds that colored intensity to the elevation gradient.

`FragColor=vec4(finalSky, 1)` outputs opaque sky. Unlike the surface shader, this shader does not apply the rational tone map or the $1/1.8$ exponent. Values can exceed one near the sun; whether those values are clipped or retained depends on the actual render-target format and later pipeline. There is no bloom calculation despite the bright disk, no clouds, and no physical wavelength-dependent scattering. The GLSL and C++ string close at lines 809-810, finishing the final shader-source pair in this interval.

Shader Compilation and GPU Targets

51. Original Lines 812-828: `g_shaderOkay` and `compileShaderModule`

The management comment introduces CPU-side shader creation. `g_shaderOkay=true` is a shared success flag. The functions below turn it false when they encounter a reported shader, program, or framebuffer failure. They do not set it true again after a later success, so it accumulates failure unless some other code explicitly resets it.

`compileShaderModule(GLenum type, const char* src)` accepts a shader-stage identifier and a pointer to its source text. `glCreateShader(type)` obtains the shader object handle `s`; typical callers supply `GL_VERTEX_SHADER` or `GL_FRAGMENT_SHADER`. `glShaderSource(s, 1, &src, nullptr)` supplies one source string. Passing the address of `src` meets the API's array-of-string-pointers interface, while the null length pointer tells OpenGL to use null-terminated text. The call copies source into the shader object; it is not a draw.

`glCompileShader(s)` asks the driver to compile it. `int ok; char log[512];` declares space for the result and a 512-byte diagnostic buffer. Although `ok` has no initial value, the next

`glGetShaderiv(s, GL_COMPILE_STATUS, &ok)` is intended to write it before testing. `if(!ok)` means "if compilation did not report success." Only that branch retrieves a compiler log, emits `[Shader Error]:` plus the message to `std::cerr`, and sets the shared flag false.

`std::endl` adds a newline and flushes the output stream, which helps immediate visibility of an error but is not necessary for every normal print. The log size is limited; lengthy driver messages can be truncated. There is no special handling here for a zero handle or a failed API call outside the compile-status check.

The function returns `s` even if compilation failed. It does not throw, abort, or delete the failed shader. The caller can proceed to linking and observe another failure. The closing conditional brace and function brace finish those scopes. This design favors gathering diagnostic state and letting later application startup decide what to do with the failure flag.

52. Original Lines 830-847: `buildProgram`, Linking, and Shader-Object Cleanup

`buildProgram(const char* vs, const char* fs)` combines vertex and fragment source. It calls `compileShaderModule` twice, with stage constants identifying each source. The two resulting handles, `v` and `f`, are attached to a newly created program `p` through `glAttachShader`. A shader object represents one compiled stage; a program combines compatible stages into something `glUseProgram` can activate for drawing.

`glLinkProgram(p)` checks and connects the stages, including their varying interfaces. Linking is a different validation step from compilation: two individually valid shader modules can still disagree on interfaces or exceed implementation limits. The local `ok` and 512-byte `log` play the same roles as in the module compiler.

`glGetProgramiv(p, GL_LINK_STATUS, &ok)` obtains link success; the failure branch fetches a program log, prints `[Program Error]:`, and sets `g_shaderOkay=false`.

The code links even if one earlier compile failed. This can provide both stage and link diagnostics but does not make the resulting program usable. Like module compilation, this helper returns a handle regardless of success. Caller logic must inspect the shared flag or program status before relying on rendering.

`glDeleteShader(v)` and `glDeleteShader(f)` request deletion of the temporary shader objects. Because the objects are attached, OpenGL may retain them until attachment references are removed; deleting a shader handle does not destroy the linked program's executable. The helper does not explicitly detach the shaders, delete a failed program, or activate `p`. `return p` gives the caller the program handle, and the final brace finishes construction. Program deletion at application shutdown is outside this range. Uniform locations queried later belong to this linked program and must not be assumed valid across relinking or replacement.

53. Original Lines 849-858: Four Program Handles and Shadow-Map Resolution

The four unsigned globals are `g_progScene`, `g_progShadow`, `g_progParticle`, and `g_progSky`. They store handles for the four shader-program roles just explained. Although their declarations do not explicitly write `=0`, file-scope objects with static storage duration are zero-initialized before ordinary runtime initialization. They still need assignments from successful program construction before use.

The shadow-framebuffer comment introduces `SHADOW_RES=2048`. Both texture dimensions later use it, giving $2048 \times 2048 = 4,194,304$ depth texels. This is a resolution, not a world-space coverage size or guaranteed precision per texel. The light's projection, defined elsewhere, determines how many world units each texel covers. A 5-by-5 PCF filter therefore has no fixed world-space softness from this constant alone.

`g_shadowFBO=0` and `g_shadowTex=0` are the future framebuffer and texture handles. A framebuffer selects image attachments as rendering destinations; a texture stores the sampled image itself. The framebuffer does not substitute for or contain a duplicated texture allocation. Keeping separate handles lets the same texture be written as an attachment during the shadow pass and sampled during a later visible pass.

If storage were 32 bits per texel, this depth image would occupy about 16 MiB before implementation overhead. The actual allocation below uses an unsized internal format, so that memory size and 32-bit depth precision are **not guaranteed** by these declarations. There are no cascaded maps, per-object maps, mip chains, or multiple depth layers declared here.

54. Original Lines 859-870: setupShadowFramebuffer and Depth-Texture Parameters

The setup function generates one framebuffer and one texture, then binds the texture to `GL_TEXTURE_2D`.

`glTexImage2D` allocates level zero using target 2D, unsized internal format `GL_DEPTH_COMPONENT`, width and height 2048, border-width argument zero, external format `GL_DEPTH_COMPONENT`, external data type `GL_FLOAT`, and null pixel data. The null pointer means there is no initial uploaded image; depth contents must be cleared or rendered before reliable sampling.

`GL_FLOAT` describes the input transfer type, not a promise that the GPU stores `GL_DEPTH_COMPONENT32F`. Because no initial pixel data is supplied and the internal format is unsized, the driver chooses a supported depth storage representation. The implementation should not be documented as fixed 16-bit, 24-bit, 32-bit, or RGB-encoded depth based only on this call.

Both minimum and magnification filters are `GL_NEAREST`. Minimum filtering without a mipmap mode permits using only level zero; no mipmap generation appears. Nearest filtering matters because the scene shader explicitly reads one depth value and compares it. Automatic shadow comparison mode is not enabled, and the GLSL sampler is an ordinary `sampler2D`.

S and T wrapping are `GL_CLAMP_TO_BORDER`, not clamp-to-edge. The four-value border array is all ones and is supplied with `glTexParameterfv`. For depth sampling, the relevant border depth is one, representing the far end of normalized depth. This makes out-of-image PCF taps ordinarily behave as unoccluded. The texture-border-width argument zero in the allocation is unrelated to this sampling border color; setting a virtual sampling border does not allocate an extra ring of pixels.

At this point the image and parameters exist, but the texture has not yet been attached to the framebuffer. No depth clear, viewport change, depth-test enable, or render occurs during these allocation lines.

55. Original Lines 871-880: Depth Attachment, No Color Buffers, and Completeness Check

`glBindFramebuffer(GL_FRAMEBUFFER, g_shadowFBO)` selects the generated framebuffer for both drawing and reading through the combined target. `glFramebufferTexture2D` attaches texture level zero to `GL_DEPTH_ATTACHMENT`; the final zero is the mip level, not a texture handle. Rendering depth while this framebuffer is active writes into the same image later sampled as `shadowMap`.

`glDrawBuffer(GL_NONE)` and `glReadBuffer(GL_NONE)` state that this framebuffer has no color draw/read target. This matches its depth-only attachment and the empty shadow fragment shader. These calls do not disable depth writes. They configure color-buffer selection for the framebuffer rather than make all rendering disappear.

`glCheckFramebufferStatus(GL_FRAMEBUFFER)` is compared with `GL_FRAMEBUFFER_COMPLETE`. If another status is returned, the branch prints `Shadow framebuffer is incomplete` followed by a newline and sets `g_shaderOkay=false`. Reusing a shader-named flag for framebuffer failure is a broad graphics-initialization success convention. The code does not print the exact failing status, clean up the partial objects, or stop inside this function.

The conditional closes, then `glBindFramebuffer(GL_FRAMEBUFFER, 0)` returns to the default framebuffer. It does not restore an arbitrary framebuffer that may have been bound before this function. Likewise, the shadow texture remains bound on the active texture unit. The function assumes a startup-oriented context where these state changes are acceptable. Its final brace ends setup; later shadow rendering must choose a 2048-square viewport, clear depth, bind the appropriate program, and supply light matrices. None of those operations is hidden in the completeness check.

56. Original Lines 882-899: setupSkyVAO and the Oversized Fullscreen Triangle

The comment says "Skybox fullscreen quad VAO," but the actual array defines **three vertices**, not four. `g_skyVAO` and `g_skyVBO` start at zero. `setupSkyVAO()` initializes a nine-float array with positions `(-1, -1, 0)`, `(3, -1, 0)`, and `(-1, 3, 0)`.

In clip-space XY, this triangle extends beyond the visible square `[-1, 1]` in both directions. Its diagonal edge is `x+y=2`, which passes through the visible square's upper-right corner. It therefore covers the full screen with one oversized triangle, avoiding a two-triangle quad's interior diagonal. Clipping trims its outside portions; input vertices at coordinate 3 are intentional, not evidence of an invalid screen mesh.

The function generates a VAO and VBO, binds them, and uploads the entire array with `sizeof(verts)` bytes and `GL_STATIC_DRAW`. Location zero receives three float components with stride `3*sizeof(float)` and offset zero, then is enabled. There is no EBO because the intended primitive can be drawn using nonindexed vertex order. The draw call itself is outside this setup function.

`glBindVertexArray(0)` leaves the configured sky VAO stored but inactive. The VBO's array-buffer binding is not explicitly restored. The shader only uses `aPos.xy`; the supplied zero Z values keep a simple three-float attribute layout consistent with its `vec3` input. Sky depth is supplied explicitly by `SKY_VERT` as 0.9999 rather than using these zeros. The initializer brace, function brace, and semicolons finish data and setup scopes. No cubemap faces, sky textures, or actual blue-gold pixels are generated by this CPU helper; the fragment shader supplies them at draw time.

Draw Helpers and Materials

57. Original Lines 901-912: Pass Selection and Material Defaults

The rendering-pipeline comment introduces `g_isShadowPass=false`. This global tells the generic primitive draw helper which set of uniforms to update. It does not itself bind a framebuffer or activate a shader. Later pass orchestration must keep the Boolean synchronized with actual OpenGL state.

`Material` is a record with in-class defaults. `diffuse=vec3(0.6)` sets RGB to `(0.6, 0.6, 0.6)`, a medium gray base. `specular=vec3(0.3)` sets all highlight channels to 0.3. `shininess=32` selects a moderately concentrated Blinn-Phong exponent. `emissive=vec3(0)` adds no self-lit contribution by default. `isSand=0` chooses ordinary material behavior, leaving both specialized sand and rock branches disabled.

These defaults are applied when a material is default-constructed, unlike the earlier tank structure with no in-class defaults. Models can then change only selected members. The `diffuse` member is uploaded to the shader's `objectColor`, `specular` to `specularColor`, and `emissive` to `emissiveColor`; different names in the C++ record and shader do not imply different values.

The structure contains no alpha, image texture handle, roughness, metalness, refractive index, or shadow-casting flag. Its integer mode can select more than just sand, and its emission does not illuminate neighboring geometry. The final brace and semicolon complete the type. A material is CPU parameter data, not an OpenGL program or buffer object, so creating one does not allocate GPU resources. Applying it requires the uniform updates in the next helper.

58. Original Lines 914-922: drawMeshPrimitive and Cached Uniform Locations

`drawMeshPrimitive(const Mesh& mesh, const glm::mat4& model, const Material& mat)` receives mesh handles, transformation, and material by constant reference. It does not copy full records or change its arguments. Its first eight statements query shader uniform locations and store them in local static `const GLint` variables. A uniform location is a program-specific integer index used for later updates, not the uniform's current numerical value.

The two shadow queries obtain `model` and `isSand` from `g_progShadow`. The six scene queries obtain `model`, `objectColor`, `specularColor`, `shininess`, `emissiveColor`, and `isSand` from `g_progScene`. All eight are initialized when execution first reaches their declarations, even if the first draw is only a shadow pass. Both programs must therefore have been successfully created before the first call.

Local static caching avoids repeated string-based queries on every object draw. However, `const` makes these locations permanent for the process's remaining calls. Rebuilding, relinking, or replacing the programs can invalidate the cached locations; the helper offers no refresh mechanism. Calling it before valid programs exist can likewise cache unsuitable values and will not automatically recover after later initialization.

`glGetUniformLocation` returns -1 for an inactive or absent uniform. Passing -1 to a uniform setter is ordinarily ignored, so a miss can be silent. The helper does not validate any of these results. It also does not cache view, projection, sun, fog, worm, or collapse locations because those are per-pass or shared values assigned by other code. These lines only prepare access to per-primitive uniforms; no drawing has occurred yet.

59. Original Lines 923-936: Pass-Specific Uniform Uploads and Indexed Drawing

When `g_isShadowPass` is true, the helper uploads one model matrix and the material's integer mode to the shadow uniform locations. `glUniformMatrix4fv(..., 1, GL_FALSE, glm::value_ptr(model))` means one four-by-four float matrix, no transposition requested, using GLM's data pointer. `glUniform1i` sends one integer. Colors and highlight parameters are unnecessary for the depth-only shader.

The `else` branch uploads that model matrix to the scene program, then sends diffuse RGB, specular RGB, shininess, emissive RGB, and mode. Each `glUniform3fv` has count one, meaning one three-component vector, not three separate vector records. `glUniform1f` sends a single float. The material's default shininess is 32, but this helper accepts whatever the caller supplies and does not clamp invalid exponents or colors.

These `glUniform` calls update the **currently active program**. They do not automatically activate the program used for querying a location. The helper contains no `glUseProgram`, so the caller must already have selected the correct program for the current pass. Likewise, it assumes appropriate framebuffer, viewport, depth state, culling state, and shared uniform values have been set externally. A Boolean/program mismatch can cause errors or incorrect rendering.

After the conditional, `glBindVertexArray(mesh.VAO)` activates the stored vertex/index configuration. `glDrawElements(mesh.drawMode, mesh.indexCount, GL_UNSIGNED_INT, 0)` draws the requested mode using `indexCount` unsigned indices starting at byte offset zero in the VAO's element buffer. The last zero is an offset, not an immediate CPU index array, because an EBO is bound through the VAO.

There is no automatic material batching, instancing, visibility culling, or mesh validity check here. Each call submits one indexed primitive draw. The helper leaves that VAO bound afterward and returns no value. Its final brace ends the function; it does not unbind or delete the mesh.

60. Original Lines 938-947: drawPart and Exact Transformation Order

The helper comment introduces a convenient way to place a primitive. `drawPart` takes a constant mesh reference, a root matrix by value, translation vector `t`, rotation vector `rDeg`, scale vector `s`, and a constant material reference. Copying `root` means the caller's matrix is not changed. `m=root` creates the local working transformation.

`glm::translate(m, t)` postmultiplies the translation under GLM's usual column-vector convention. Three conditionals then apply rotations only when their respective degree values are nonzero. Y rotation is appended first, then X, then Z. Each angle is converted from degrees through `glm::radians`, and axis vectors are $(0, 1, 0)$, $(1, 0, 0)$, and $(0, 0, 1)$. Skipping zero rotations avoids unnecessary matrix operations but does not introduce tolerance-based snapping for tiny angles.

The final scale is appended with `glm::scale(m, s)`. The combined matrix is `root * T * Ry * Rx * Rz * S`. Since matrices act on column vectors from right to left, a local mesh vertex is scaled first, then rotated around Z, then X, then Y, then translated, then transformed by the root. The **written call order** and the **order experienced by a vertex** are therefore opposite. Rotation order matters because three-dimensional rotations generally do not commute.

Translation here is expressed in the root's coordinate system. A root rotation can rotate the translated offset, making the helper suitable for assembling attached parts. Negative scales can reverse winding; zero scales can make the scene shader's inverse normal matrix undefined. The helper does not prevent those cases or automatically adjust culling.

`drawMeshPrimitive(mesh, m, mat)` then sends the assembled matrix and material to the active pass and draws. There is no separate object stored for this part: it is an immediate transformed reuse of a primitive mesh. The final brace ends the placement-and-draw helper.

Shared Color Palette

61. Original Lines 949-967: Every Palette Constant and Its Actual Meaning

Lines 949-951 introduce the cinematic palette. Each declaration defines a constant three-component RGB vector. The values are color inputs, not final screen pixels: lighting, shadowing, tone mapping, fog, and render-target behavior can change their visible appearance. All fifteen declarations are immutable through ordinary assignment. Their exact values and intended roles are:

- Line 952, COL_DUNE_SAND=(0.76, 0.49, 0.23): warm ochre-brown sand, with red strongest and blue weakest.
- Line 953, COL_DUNE_SHADOW=(0.55, 0.36, 0.18): a darker warm companion color. Its name does not perform shadow testing; only actual uses elsewhere decide where it appears.
- Line 954, COL_ATREIDES_HULL=(0.22, 0.23, 0.22): dark nearly neutral hull gray with a slight green emphasis. The "matte carbon" comment describes artistic intent; shininess and specular settings determine actual highlight behavior.
- Line 955, COL_ATREIDES_DARK=(0.13, 0.14, 0.13): a darker, similarly green-tinted gray for contrasting aircraft parts.
- Line 956, COL_CANOPY_GLASS=(0.06, 0.08, 0.11): very dark blue-gray canopy color. The "armored glass" comment does not enable transparency, refraction, or Fresnel effects.
- Line 957, COL_JET_NOZZLE=(0.08, 0.08, 0.08): equal-channel dark gray for jet nozzle geometry.
- Line 958, COL_AFTERBURNER=(1.00, 0.55, 0.12): bright orange-yellow reheat coloration. Brightness or glow requires appropriate emissive/material use; this vector alone does not create light or bloom.
- Line 959, COL_SPICE_ORANGE=(0.96, 0.42, 0.04): strongly saturated spice orange, with very little blue.
- Line 960, COL_SPICE_GLOW=(1.00, 0.50, 0.08): a somewhat brighter orange intended for spice-related glow elements. The name is not an emissive assignment by itself.
- Line 961, COL_CRAWLER_TRACK=(0.11, 0.11, 0.10): near-neutral very dark tread color, slightly warmer than exact gray.
- Line 962, COL_HARV_CHASSIS=(0.42, 0.34, 0.25): muted warm brown for industrial chassis geometry.
- Line 963, COL_HARV_RUST=(0.48, 0.24, 0.12): red-brown rust accent, with each successive channel roughly half the preceding one.
- Line 964, COL_TANK_STEEL=(0.52, 0.46, 0.38): warm light-gray/brown steel coloration. There is no physically metallic material classification in this palette.
- Line 965, COL_ROCK_STRATA1=(0.42, 0.28, 0.17): a warmer, lighter rock-stratum color.
- Line 966, COL_ROCK_STRATA2=(0.32, 0.20, 0.11): a darker companion rock-stratum color.

The semicolon on each line completes its declaration. Line 967 is blank, ending this chapter's original-source interval before the aircraft assembly begins. No palette declaration uploads a uniform until later drawing selects a color and applies a material. Constants provide consistent art direction without claiming measured spectral reflectance or standard color-space calibration.

Implementation Boundaries

The source-order walkthrough covers every nonblank original line from 1 through 967. The following points connect those details into the renderer's actual architecture without adding claims not established by the code:

- The CPU terrain function is continuous over X/Z, but the GPU terrain is one finite 700-unit patch sampled at five-unit intervals by default. Mathematical continuity does not mean infinite geometry, camera-centered regeneration, or an exact per-pixel height surface.
- Terrain normals are central finite differences, and rasterization smooths/interpolates them. Collapse deforms the two vertex passes consistently but does not update normals, collision heights, landing-pad queries, or particle ground queries.
- The CPU dust pool has 2,400 records with deterministic pseudorandom initialization and recycled lifetimes. Branch priority selects crawler, worm, downwash, or ordinary dust; comments should not be substituted for their exact modulo and time conditions.
- Particle motion is velocity-based visual integration with gust scaling and a terrain lift rule. There is no sand-grain mass, gravity integration, mutual collision, fluid solver, or conservation model in these functions.

- Procedural primitives are reusable GPU meshes. Hard edges use duplicated normals; sphere poles submit collapsed faces; wings have open ends and simplified normals; the rock perturbation does not guarantee a welded longitudinal seam.
- Surface lighting is ambient plus directional wrapped/Lambert diffuse plus Blinn-Phong specular plus emission. It is not a physically based renderer, and opaque alpha is used even for glass-colored surfaces.
- Shadows use a single 2048-square depth image, nearest depth fetches, receiver-slope adjustment, bias, and 25 manual comparisons per shadowed surface fragment. Unsized depth allocation leaves actual depth precision to the driver; fixed PCF is not a physically variable penumbra.
- The sky is a ray-shaded fullscreen triangle with an elevation gradient and analytic sun terms, not a cubemap, cloud simulation, or scattering solver. It does not share the surface shader's final tone-mapping expression.
- OpenGL handles and cached uniform locations are lightweight shared state. Correct operation depends on successful context/program setup, matching active pass state, valid transformations, and explicit lifecycle work outside this chapter.

These limitations do not make the implementation unsuitable for a real-time graphics laboratory. They identify the deliberate approximations and concrete edge cases a reader must understand before extending or diagnosing it. The key learning sequence is: compute simulation and geometry on the CPU, upload reusable data, transform vertices in shaders, shade fragments with explicit mathematical terms, then orchestrate the passes with the correct OpenGL state.

Scene Assembly and Application Runtime

This chapter explains the scene-building and application-lifecycle portion of `src/arrakis.cpp`. Its source references use the **original, pre-relocation line numbers 968-1892** from the root-level `arrakis.cpp` inspected for this documentation. The relocated `src/arrakis.cpp` was also checked: the covered range still has the same line numbers and statements. The original ranges below identify the inspected statements, comments, and function boundaries. The complete source listings supplied elsewhere in the documentation remain the authority for the final physical file layout.

The covered code turns previously generated meshes into recognizable vehicles, machinery, landscape objects, and rescue markers, then connects them to GLFW input, simulation updates, spatial audio, OpenGL rendering, screenshots, automated render checks, and cleanup. It does not load vehicle models from external model files. The geometric pieces are reused meshes with different transformations and materials. The supporting application headers live alongside the application source in `src/`; mission tests are documented under `tests/arrakis_tests.h`. Third-party implementation files and audio assets belong under `third_party/` and `assets/audio/`, respectively. Those layout names do not imply additional runtime behavior in the original code explained here.

Reading Transforms and Materials

Shared Conventions Used Throughout This Chapter

Context for original lines 968-1354: the actual transform helper and default material definitions are immediately before this chapter's assigned range, at original lines 906-947. Understanding them is necessary to read every scene draw call accurately.

`drawPart(mesh, root, t, rDeg, s, material)` starts with the supplied parent matrix `root`, appends translation `t`, appends any nonzero Y rotation, then X rotation, then Z rotation, and finally appends scale `s`. In matrix notation the result is $root * T * R_y * R_x * R_z * S$. The rotation tuple is still written as (X, Y, Z) in the calls; it is not a description of the multiplication order. Degrees are converted to radians by the helper before calling GLM. With column-vector positions, the scale is applied to a mesh point first, then the local Z, X, and Y rotations, then the local translation, then all inherited parent transformations. A translated part therefore rotates about its own local origin before being placed at its attachment location. When a parent is tilted or scaled, the child's apparent world-space position and orientation inherit that parent change.

The notation in the tables below is literal: **T** is the translation tuple, **R** is the (X, Y, Z) degree tuple, and **S** is the scale tuple. All coordinates are in the parent's local space unless a section explicitly constructs a world-space root. Vehicle construction uses X for left/right, Y for up/down, and Z for front/back; the ornithopter's nose is toward negative Z. Numbers are scene units, not a declared real-world measurement system.

The generated cube is centered at the origin and has unit side length. The sphere has radius 0.5, so its scale tuple gives its full axis diameters before other transforms. The generated cylinder has radius 0.5, height 1, and its long axis along local Y. A cylinder with $S(2.2, 3.2, 2.2)$ therefore has diameter 2.2 and length 3.2; rotating it 90 degrees around X places that length along Z. Nonuniform X/Z scaling changes a round cylinder into an elliptical one. A mesh called a cylinder remains the same capped-cylinder geometry even when a source comment calls the result a probe, funnel, nozzle, or drum. Likewise, an entire sphere is drawn for each nominal domed tank head; overlapping spheres and a cylinder produce the visible rounded ends rather than explicit hemisphere meshes.

Every `Material` initially has diffuse $(0.6, 0.6, 0.6)$, specular $(0.3, 0.3, 0.3)$, shininess 32, emissive $(0, 0, 0)$, and `isSand = 0`. A construction function only overrides the fields shown in its body. In material tables, `default` means exactly these unchanged values, not a missing value or a random shader setting. A scalar `glm::vec3(v)` repeats `v` in all three color channels. Diffuse controls the surface color, specular and shininess control the highlight contribution, emissive adds self-colored brightness in the scene shader, and `isSand` selects special shader treatment. Emission does not create an additional OpenGL light source and does not, by itself, illuminate neighboring geometry.

`drawPart` ultimately calls `drawMeshPrimitive`. During the shadow pass, that helper sends the model matrix and material surface classification to the shadow program. During the normal scene pass, it also sends the color, specular, shininess, and emission values to the scene program. The same assembled object can therefore participate in both passes without duplicating its construction logic.

Ornithopter Construction

Function Inputs and Six Surface Materials

Original source: lines 968-1001. The section banner describes an *Atreides*-style ornithopter with eight tandem dragonfly blades, an insect-like hull, and glowing jets. These are design descriptions; the implementation that follows is a collection of scaled primitive meshes and a dedicated wing mesh.

`drawMovieOrnithopter(root, wingPhase, roll, pitch, boosting)` receives the assembled aircraft-to-world transform, the animation phase for the wings, roll and pitch values, and the boost state. In this function, roll and pitch are not read. Aircraft attitude has already been applied to `root` by `drawFullScene`; the redundant arguments do not add a second banking or pitching transform. `wingPhase` drives the flap and twist formulas. `boosting` chooses between two exhaust lengths and emission values.

The six local material objects are rebuilt on each invocation. They do not represent six texture files or persistent GPU objects. Each supplies the fields used by the primitive helper for that draw.

Material	Diffuse RGB	Specular RGB	Shininess	Emissive RGB	Role
<code>matHull</code>	(0.22, 0.23, 0.22)	(0.4, 0.4, 0.4)	64	default zero	Main dark gray body and selected structural parts.
<code>matDark</code>	(0.13, 0.14, 0.13)	(0.3, 0.3, 0.3)	32	default zero	Darker probe, canopy frame, gimbals, tail pieces, and skids.
<code>matCanopy</code>	(0.06, 0.08, 0.11)	(0.9, 0.9, 0.9)	128	default zero	Very dark blue-gray cockpit surface with a sharp highlight.
<code>matFlame</code>	(1, 0.55, 0.12)	default (0.3, 0.3, 0.3)	default 32	Boosting: (1.2, 0.6, 0.15); otherwise (0.6, 0.25, 0.05)	Orange exhaust geometry with stronger self-brightness under boost.
<code>matJetNozzle</code>	(0.08, 0.08, 0.08)	(0.5, 0.5, 0.5)	64	default zero	Dark terminal engine nozzles.
<code>matBlade</code>	(0.18, 0.19, 0.18)	(0.7, 0.7, 0.7)	90	default zero	Thin dark metallic-looking wing blades.

All six keep `isSand = 0`. The canopy is not rendered with an alpha-bearing glass material here. Its name and high specular response give it a glass-like appearance, but the call supplies no transparency, refraction, or view through the canopy. The flame's emission can exceed one in some channels because the assigned float values are not clamped in this construction function.

Fuselage, Cockpit, and Dorsal Intakes

Original source: lines 1002-1018. These comments and seven draw calls build the central pod, front details, canopy, and paired intakes. Every call uses the incoming aircraft `root` directly, so none introduces a second articulated parent.

Original line	Mesh and visual component	T	R	S	Material
1004	Sphere: central elongated body pod	(0, 0, -0.4)	(0, 0, 0)	(1.3, 0.85, 3.2)	matHull
1006	Cylinder: forward nose segment	(0, -0.05, -2.1)	(85, 0, 0)	(0.7, 1.4, 0.45)	matHull
1008	Cylinder: narrow forward sensor probe	(0, -0.1, -3.1)	(90, 0, 0)	(0.06, 1.2, 0.06)	matDark
1011	Sphere: tinted cockpit canopy	(0, 0.32, -1.2)	(-10, 0, 0)	(0.85, 0.65, 1.6)	matCanopy
1013	Cube: slim canopy spine	(0, 0.58, -1.1)	(-10, 0, 0)	(0.12, 0.18, 1.5)	matDark
1016	Cylinder: positive-X dorsal intake	(0.42, 0.35, -0.2)	(82, 0, 0)	(0.35, 1.2, 0.28)	matHull
1017	Cylinder: negative-X dorsal intake	(-0.42, 0.35, -0.2)	(82, 0, 0)	(0.35, 1.2, 0.28)	matHull

The central sphere's nonuniform dimensions turn it into a long, low ellipsoid. The nose cylinder is nearly horizontal, with a slight departure from the probe's exact 90-degree X rotation. Its name says tapered, but this particular draw does not change the cylinder's radius along its length. The probe is long compared with its 0.06 diameter, producing the needle-like detail at the front. The canopy lies above the forward body, and the thin cube spine is higher still, making a dark structural line over the shiny surface.

The comment about multiple canopy facets does not correspond to multiple separate canopy calls in this range: one tessellated sphere is drawn. Its generated triangles and its ellipsoidal scale define its actual surface. The two intake cylinders differ only in the sign of their X positions, placing them symmetrically on the upper body. They are solid capped meshes; no separate open interior or airflow simulation is added by these calls.

Wing Gimbals, Turbines, Nozzles, and Boost Exhaust

Original source: lines 1019-1035. Four shoulder cylinders suggest front and aft wing mounting hardware. Two larger cylinders create engine bodies, two shorter cylinders create the nozzles, and two final cylinders create visible exhaust. Their exact transforms are below.

Original line	Mesh and component	T	R	S	Material
1020	Cylinder: front positive-X wing gimbal	(0.72, 0.1, -0.3)	(0, 0, 90)	(0.45, 0.65, 0.45)	matDark
1021	Cylinder: front negative-X wing gimbal	(-0.72, 0.1, -0.3)	(0, 0, 90)	(0.45, 0.65, 0.45)	matDark
1022	Cylinder: aft positive-X wing gimbal	(0.68, 0.05, 0.5)	(0, 0, 90)	(0.42, 0.62, 0.42)	matDark
1023	Cylinder: aft negative-X wing gimbal	(-0.68, 0.05, 0.5)	(0, 0, 90)	(0.42, 0.62, 0.42)	matDark
1026	Cylinder: positive-X turbine body	(0.52, -0.15, 0.9)	(90, 0, 0)	(0.42, 1.6, 0.42)	matHull

Original line	Mesh and component	T	R	S	Material
1027	Cylinder: negative-X turbine body	(-0.52, -0.15, 0.9)	(90, 0, 0)	(0.42, 1.6, 0.42)	matHull
1029	Cylinder: positive-X exhaust nozzle	(0.52, -0.15, 1.72)	(90, 0, 0)	(0.36, 0.25, 0.36)	matJetNozzle
1030	Cylinder: negative-X exhaust nozzle	(-0.52, -0.15, 1.72)	(90, 0, 0)	(0.36, 0.25, 0.36)	matJetNozzle
1033	Cylinder: positive-X luminous exhaust	(0.52, -0.15, 1.8 + flameLen * 0.5)	(90, 0, 0)	(0.24, flameLen, 0.24)	matFlame
1034	Cylinder: negative-X luminous exhaust	(-0.52, -0.15, 1.8 + flameLen * 0.5)	(90, 0, 0)	(0.24, flameLen, 0.24)	matFlame

A 90-degree Z rotation puts each gimbal's long cylinder axis across the aircraft rather than upright. The front pair is slightly larger and higher than the aft pair. The visible mounting cylinders do not individually rotate with wing strokes; the wing matrices constructed later are separate transforms sharing the aircraft parent.

Both turbine bodies run along Z beneath the fuselage. Their nozzle centers are farther toward positive Z, the rear of the aircraft. Line 1032 sets `flameLen` to 1.4 under boost and 0.6 otherwise. Consequently the exhaust centers are at Z 2.5 or 2.1, while the scaled cylinders extend between Z 1.8 and Z 3.2 or 2.4. Moving the center by half the chosen length keeps the forward end at the same location. The glowing shapes exist even when the aircraft is not boosting. They become longer and use the stronger emission values when the boolean is true; no branch removes them, animates their noise, or makes a tapered flame mesh.

Tail Boom, Stabilizers, and Landing Skids

Original source: lines 1036-1048. The remaining fixed aircraft pieces extend behind the engines and below the body.

Original line	Mesh and component	T	R	S	Material
1037	Cylinder: main tail boom	(0, 0, 2.4)	(90, 0, 0)	(0.32, 2.6, 0.28)	matHull
1038	Cylinder: narrower aft boom	(0, 0.05, 4.4)	(90, 0, 0)	(0.18, 2.2, 0.16)	matDark
1040	Cylinder: terminal stinger	(0, 0.05, 5.7)	(90, 0, 0)	(0.08, 1.1, 0.08)	matDark
1043	Cube: positive-X canted tail fin	(0.5, 0.55, 4.2)	(0, 0, 38)	(0.08, 0.9, 0.65)	matHull
1044	Cube: negative-X canted tail fin	(-0.5, 0.55, 4.2)	(0, 0, -38)	(0.08, 0.9, 0.65)	matHull
1046	Cube: positive-X ventral skid	(0.45, -0.6, -0.4)	(0, 0, 0)	(0.08, 0.45, 2.2)	matDark
1047	Cube: negative-X ventral skid	(-0.45, -0.6, -0.4)	(0, 0, 0)	(0.08, 0.45, 2.2)	matDark

The tail is assembled from progressively narrower, overlapping cylinders instead of one continuously tapered extrusion. The final stinger is a cylinder too. The two fins are thin cubes tilted in opposite Z directions to make a V-like arrangement. They have no separate steering animation in this function. The skids are also fixed cubes, long in Z and

thin in X, positioned below the pod. No extension or retraction branch is present. In total, the fixed portion of this aircraft function issues 24 primitive draws before the wings.

Flap Waveforms and Eight Wing Definitions

Original source: lines 1049-1081. The wing section begins with its own descriptive banner and defines a 34-degree flap amplitude. $\text{flap1} = \sin(\text{wingPhase}) * 34$ and $\text{flap2} = \sin(\text{wingPhase} + \pi * 0.75) * 34$. A phase difference of $0.75 * \pi$ is 135 degrees, not an exact 180-degree opposition. The comment's term anti-phase is therefore an informal description of staggered strokes. The aft definitions introduce an additional sign reversal of selected flap values.

The local `WingDef` structure stores five pieces of information: `side` is +1 for the right/positive-X blade and -1 for the left/negative-X blade; `pivot` is the attachment point; `flapAng` is the current waveform sample; `sweepBack` is a fixed backward-sweep angle in degrees; and `dihedral` is the resting vertical angle, also in degrees. The eight-element array is recreated from the current phase at each draw.

Pair and side	side	Pivot	flapAng	sweepBack	dihedral
Forward upper, right	1	(0.95, 0.22, -0.35)	flap1	14	12
Forward upper, left	-1	(-0.95, 0.22, -0.35)	flap1	14	12
Forward lower, right	1	(0.95, -0.05, -0.25)	flap2	18	-10
Forward lower, left	-1	(-0.95, -0.05, -0.25)	flap2	18	-10
Aft upper, right	1	(0.90, 0.18, 0.50)	-flap2	28	8
Aft upper, left	-1	(-0.90, 0.18, 0.50)	-flap2	28	8
Aft lower, right	1	(0.90, -0.08, 0.60)	-flap1	32	-12
Aft lower, left	-1	(-0.90, -0.08, 0.60)	-flap1	32	-12

The upper and lower attachment points are separated vertically and slightly longitudinally. The aft pivots are closer to the centerline and farther back. Greater sweep values for the aft blades keep their resting directions distinct from the forward blades. A mirrored pair shares its scalar phase and dihedral settings; the side multiplier in the matrix logic is what turns the two sides into corresponding opposite-space movements.

Wing Matrix Order, Mirroring, and Culling

Original source: lines 1082-1101. The range-based loop visits all eight array entries. It copies the aircraft matrix to `wm`, translates to the current wing's pivot, and appends a Z rotation of `side * (dihedral + flapAng)` degrees. That is the flap motion about the aircraft's longitudinal axis. It then appends a Y rotation of `side * sweepBack` degrees. Finally it computes $\text{pitchTwist} = \cos(\text{wingPhase}) * 8 * \text{side}$ and appends that X rotation.

All blades use the same cosine phase for twist; the twist is not computed from the wing's own `flapAng`, and the aft blades do not receive an additional twist-phase shift. The twist amplitude is eight degrees. The sign flips left versus right. The resulting wing matrix is $\text{root} * T(\text{pivot}) * R_z(\text{flap and dihedral}) * R_y(\text{sweep}) * R_x(\text{twist}) * S(\text{side} * 5.2, 1, 1)$.

The final scale stretches the generated wing's original X span from one to 5.2 units. On the left, negative X scale both extends the blade to the opposite side and reverses the winding of its triangles. Instead of selecting a different front-face convention for those blades, the code disables face culling before drawing each wing, draws `g_meshWing` using

matBlade, and then enables face culling again. Both sides of the thin blades are therefore drawable. This is an explicit state setting, not a saved-state restoration: the loop always leaves culling enabled. It does not change the configured `glCullFace(GL_BACK)` choice.

The wing draw calls use `drawMeshPrimitive` directly because their composite transform is already built. Together with the 24 fixed draws, the aircraft has 32 mesh draws per invocation. Since the full scene is invoked for both depth and color rendering, a visible aircraft is assembled and submitted in each of those passes with the same frame phase. The closing braces at lines 1100-1101 end the wing loop and aircraft function; they introduce no additional update of animation state.

Harvester Construction

Materials, Main Hopper, and Refinery Deck

Original source: lines 1103-1119. The harvester banner identifies four crawler units, a rotary scoop, and a multi-level industrial body. `drawSpiceHarvester(root, crawlerAnim)` accepts the already positioned and slope-adjusted vehicle matrix plus an animation amount. The caller supplies accumulated harvester travel, not wall-clock time. The visible rotation formulas multiply this distance-like value by their own constants.

Material	Diffuse RGB	Specular RGB	Shininess	Emissive RGB
matChassis	(0.42, 0.34, 0.25)	(0.2, 0.2, 0.2)	20	default zero
matTread	(0.11, 0.11, 0.10)	(0.15, 0.15, 0.15)	10	default zero
matRust	(0.48, 0.24, 0.12)	(0.2, 0.2, 0.2)	16	default zero
matSpice	(0.96, 0.42, 0.04)	default (0.3, 0.3, 0.3)	default 32	(0.8, 0.35, 0.05)
matGlass	(0.1, 0.2, 0.25)	(0.8, 0.8, 0.8)	90	default zero
matLight	(1, 0.95, 0.7)	default (0.3, 0.3, 0.3)	default 32	(1.2, 1.1, 0.8)

All retain `isSand = 0`. The chassis is warm brown, the tread almost black, and the rust reddish brown. Bright orange spice details and pale floodlights use emission rather than additional point-light uniforms. The bridge glass, like the aircraft canopy, is shiny colored opaque geometry in this construction path.

Line 1116 draws the main body using a cube with T (0, 2.6, 0), R (0, 0, 0), S (9.5, 3.8, 6.2), and `matChassis`. The large width and length establish a broad rectangular hopper. Line 1118 draws another chassis cube at T (0, 4.8, -0.4), R zero, S (8.2, 1.2, 5.0) for the upper deck. It is narrower, shorter, elevated, and slightly forward of the main body's center. These meshes are closed cubes, not hollow storage compartments. Their names do not add an interior refinery simulation.

Four Track Units, Wheels, and Traveling Pads

Original source: lines 1120-1139. The track loops enumerate X offsets -4.6 and 4.6 and Z offsets -2.4 and 2.4. Every combination creates one track parent `tm = translate(root, (ox, 0.95, oz))`, yielding four units. Their left/right placement is inherited from `ox`, while their front/rear placement is inherited from `oz`.

Each unit first draws a tread-colored housing cube with local T zero, R zero, and S (1.8, 1.7, 3.8). It is centered at the track parent, making the same housing usable at all four corners. A wheel loop starts `wz` at -1.4, continues while `wz <= 1.4`, and adds 0.93 each iteration. It produces four wheel locations approximately -1.4, -0.47, 0.46, and 1.39; the next value exceeds the bound. The endpoint is not exactly 1.4 because the spacing and floating-point accumulation determine the actual sample locations.

At each wheel location line 1130 draws a chassis cylinder with $T(ox > 0 ? 0.95 : -0.95, -0.2, wz)$, $R(0, 0, 90)$, and $S(1.2, 0.35, 1.2)$. The sign test depends on the enclosing track's X location. It places each wheel on that track's outward-facing side. The Z rotation lays the 0.35 cylinder thickness along X, while the other scale values establish a 1.2 diameter. The full world X position includes the track parent offset as well as this local side offset.

Line 1131 adds a narrow rusty cube on the outer face: $T(ox > 0 ? 1.15 : -1.15, -0.2, wz)$, $R(crawlerAnim * 80, 0, 0)$, $S(0.04, 0.95, 0.12)$. This is the changing decorative wheel-face detail. The 80 coefficient supplies degrees per unit of `crawlerAnim` through `drawPart`; no conversion to radians is done at this line because the helper does it. Its explicit rotation axis is local X before the track parent transforms, aligned with the cylinder axle after that cylinder's 90-degree Z rotation. The wheel cylinder itself does not receive an animation angle; the bar's changing orientation supplies the visible spinning detail while the smooth wheel body remains unchanged.

Ten pad cubes are drawn per track. For integer pad values zero through nine, line 1134 computes $a = pad * two_pi / 10 + crawlerAnim * 0.7$. Here a is in radians and feeds sine and cosine directly. The pad center is $(0, 0.85 * \sin(a), 1.8 * \cos(a))$, an ellipse in the unit's Y/Z plane. The angle is $-\text{degrees}(\text{atan2}(0.85 * \cos(a), -1.8 * \sin(a)))$. The two `atan2` arguments are the Y and Z components of the derivative of that elliptical path. Negating the resulting angle sets the cube's local X rotation so its long Z direction follows the path tangent.

Line 1136 therefore draws each pad with that computed $T, R(\text{angle}, 0, 0), S(1.9, 0.12, 0.38)$, and `matRust`. Pads span the track's width but are thin in Y and short in Z. Their centers revolve around the housing as `crawlerAnim` grows. The code does not translate a continuous tread texture or construct a linked belt mesh; it moves ten separate cubes around each ellipse. One unit submits one housing, four cylinders, four bars, and ten pads, or 19 draws. The nested loops submit 76 track-related draws in total. The closing braces finish the pad loop, front/rear loop, and left/right loop without changing the harvester root.

Cutter, Exit Door, Ramp, and Side Separators

Original source: lines 1141-1153. This section constructs the low forward harvesting equipment and several side details. Although the cutter comment mentions teeth, no separate tooth draw calls occur in this range: the primary cutter is the reused cylinder.

Original line	Mesh and component	T	R	S	Material
1143	Cylinder: wide front cutter drum	$(0, 1.1, -4.2)$	$(crawlerAnim * 70, 0, 90)$	$(2.2, 8.8, 2.2)$	<code>matRust</code>
1145	Cube: dark side door	$(4.78, 1.8, 1.2)$	$(0, 0, 0)$	$(0.12, 2.4, 1.5)$	<code>matDoor</code>
1146	Cube: outward side ramp	$(5.5, 0.45, 1.2)$	$(0, 0, -16)$	$(2, 0.15, 1.7)$	<code>matChassis</code>
1148	Cube: luminous intake scoop	$(0, 0.9, -4.8)$	$(15, 0, 0)$	$(8.2, 0.6, 1.4)$	<code>matSpice</code>
1151	Cylinder: positive-X separator	$(4.8, 2.2, -1.8)$	$(0, 0, -22)$	$(1.2, 2.4, 1.2)$	<code>matRust</code>
1152	Cylinder: negative-X separator	$(-4.8, 2.2, -1.8)$	$(0, 0, 22)$	$(1.2, 2.4, 1.2)$	<code>matRust</code>

Line 1144 constructs `matDoor` with diffuse $(0.06, 0.07, 0.06)$ and leaves every other field at its default. The door is an almost black thin rectangle on the positive-X side; the ramp extends farther out and slopes through its negative Z rotation. Neither has an opening animation in this function. The scoop is a thin orange slab angled about X at the front and lower than the drum's center.

The drum call appends X rotation before Z rotation in the helper's matrix multiplication. At zero `crawlerAnim`, the 90-degree Z rotation turns its original Y axis across the vehicle along X; subsequent changes to the X angle rotate

around that resulting axis. The 70 coefficient is in degrees per supplied animation unit. The two separators are straight cylinders tilted oppositely around Z. Their comment calls them funnels, but there is no tapered or hollow funnel primitive in these draw calls.

Bridge, Viewport, Floodlights, and Exhaust Stacks

Original source: lines 1154-1168. The elevated details complete the harvester and close its draw function.

Original line	Mesh and component	T	R	S	Material
1155	Cube: observation bridge body	(2.8, 5.8, -2.2)	zero	(2.6, 1.4, 2)	matChassis
1157	Cube: forward bridge viewport	(2.8, 5.9, -3.25)	zero	(2.4, 0.65, 0.2)	matGlass
1159	Sphere: first forward floodlight	(1.8, 5.2, -3.3)	zero	(0.35, 0.35, 0.35)	matLight
1160	Sphere: second forward floodlight	(3.8, 5.2, -3.3)	zero	(0.35, 0.35, 0.35)	matLight
1163	Cylinder: positive-X exhaust stack	(1.6, 6.2, 1.8)	zero	(0.75, 2.6, 0.75)	matChassis
1164	Cylinder: negative-X exhaust stack	(-1.6, 6.2, 1.8)	zero	(0.75, 2.6, 0.75)	matChassis
1166	Cylinder: positive-X glowing vent rim	(1.6, 7.55, 1.8)	zero	(0.85, 0.2, 0.85)	matSpice
1167	Cylinder: negative-X glowing vent rim	(-1.6, 7.55, 1.8)	zero	(0.85, 0.2, 0.85)	matSpice

The bridge is offset to the positive-X front of the refinery deck. Its viewport is thin in Z and just forward of the bridge. The two small emissive spheres sit on either side below that viewport. The comment says they illuminate the desert, but the local code submits no spotlight parameters; their actual local effect is visibly bright geometry. Overall scene lighting remains the directional sun and ambient contribution described later.

The vertical stacks sit at the rear of the top deck. Because no rotation is supplied, their 2.6 Y scales make them upright. The slightly wider, much shorter orange cylinders sit at their tops as luminous rims. This function does not emit particles from those exact stack positions. Particle placement is handled separately by the particle simulation. With two body cubes, 76 track draws, six cutter/door/ramp/separator draws, and eight elevated-detail draws, the harvester function submits 92 meshes per invocation.

Spice Tank Construction

Four Materials and the Transport Cradle

Original source: lines 1170-1192. The tank banner describes a heavy horizontal vessel with rounded heads, supporting members, and an illuminated spice indicator. `drawMovieSpiceTank(root)` has no animation parameter. Any placement, yaw, or instance scale must already be present in `root`.

`matCradle` has diffuse (0.24, 0.23, 0.22), specular (0.3, 0.3, 0.3), and shininess 32. `matVessel` uses tank steel diffuse (0.52, 0.46, 0.38), specular (0.6, 0.6, 0.6), and shininess 64. `matSeam` is darker, with diffuse (0.18, 0.17, 0.16), specular (0.2, 0.2, 0.2), and shininess 20. `matSpice` uses diffuse (0.96, 0.42, 0.04) and emission (1.2, 0.55, 0.08), keeping default specular and shininess. None changes `isSand`, and only the spice material changes default zero emission.

Original line	Mesh and cradle component	T	R	S	Material
1182	Cube: positive-X ground skid	(1.35, 0.18, 0)	zero	(0.35, 0.35, 4.4)	matCradle
1183	Cube: negative-X ground skid	(-1.35, 0.18, 0)	zero	(0.35, 0.35, 4.4)	matCradle
1185	Cube: rear cross support	(0, 0.25, 1.6)	zero	(3, 0.25, 0.35)	matCradle
1186	Cube: forward cross support	(0, 0.25, -1.6)	zero	(3, 0.25, 0.35)	matCradle
1189	Cube: positive-X inclined stanchion, at each Z	(1.3, 1.1, z)	(0, 0, -22)	(0.28, 1.8, 0.35)	matCradle
1190	Cube: negative-X inclined stanchion, at each Z	(-1.3, 1.1, z)	(0, 0, 22)	(0.28, 1.8, 0.35)	matCradle

The stanchion loop uses exactly two Z values, -1.3 and 1.3, so its two draw statements produce four inclined support members. The long skids run along Z; the cross supports run along X; and the upright members lean through opposite Z rotations. These are independent solid boxes that visually overlap where necessary. There is no separate welding, constraint, or load-bearing solver associated with the comments. The cradle contains eight primitive draws.

Vessel Body, Domed Ends, Weld Bands, and Indicator

Original source: lines 1193-1210. The rest of the tank uses eight draws to form its pressure vessel and visible fittings.

Original line	Mesh and vessel component	T	R	S	Material
1195	Cylinder: horizontal central vessel	(0, 1.55, 0)	(90, 0, 0)	(2.2, 3.2, 2.2)	matVessel
1197	Sphere: positive-Z rounded head	(0, 1.55, 1.6)	zero	(2.2, 2.2, 1.3)	matVessel
1198	Sphere: negative-Z rounded head	(0, 1.55, -1.6)	zero	(2.2, 2.2, 1.3)	matVessel
1201	Cylinder: positive-Z reinforcing band	(0, 1.55, 0.8)	(90, 0, 0)	(2.28, 0.18, 2.28)	matSeam
1202	Cylinder: negative-Z reinforcing band	(0, 1.55, -0.8)	(90, 0, 0)	(2.28, 0.18, 2.28)	matSeam
1205	Cylinder: top loading hatch	(0, 2.72, 0)	zero	(0.65, 0.25, 0.65)	matSeam
1206	Sphere: bright relief-valve detail	(0, 2.92, 0)	zero	(0.4, 0.25, 0.4)	matSpice
1209	Cube: vertical side sight indicator	(1.15, 1.55, 0)	zero	(0.08, 1.5, 0.18)	matSpice

There are eight rows in this table and eight draws; together with the eight cradle draws, the complete tank submits 16 meshes. The central vessel extends from local Z -1.6 to 1.6. The full ellipsoidal head meshes are centered at those endpoints, overlapping the cylinder and projecting out by 0.65 along Z. They keep the same X/Y diameter as the body. The narrow band cylinders have a slightly larger 2.28 diameter and only 0.18 axial length, causing their outer circumferences to show as dark reinforcing bands around the shell.

The top hatch is a short upright cylinder. The flattened emissive sphere above it supplies the bright valve-like shape. The side sight indicator is a thin, tall cube at positive X. Its material remains constant; no fill-level calculation, changing length, pulsing brightness, or animated spice level appears in this function. The comments identify the intended industrial interpretation of the visible detail, while the draw calls determine its actual implementation. Line 1210 closes the function.

Desert Rock Construction

Strata Materials and Four Eroded Mesh Pieces

Original source: lines 1212-1225. `drawDesertRockFormation(root, variant)` reuses the dedicated eroded-rock mesh four times to suggest one larger wind-carved formation. `matStrata1` has diffuse (0.42, 0.28, 0.17), specular (0.15, 0.15, 0.15), and shininess 16. `matStrata2` has darker diffuse (0.32, 0.20, 0.11), specular (0.12, 0.12, 0.12), and shininess 12. Both retain zero emission.

Line 1220 performs a chained assignment, setting both materials' `isSand` fields to 2. The integer is a surface category consumed by the rendering shaders, not a C++ boolean assertion that the rocks are sand. It distinguishes their treatment from ordinary metal or cloth (0) and the main dune terrain (1). The shader chapter explains the category's detailed lighting and procedural color effect.

Original line	Visual component	T	R	S	Material
1221	Dominant base crag	(0, 2.2, 0)	(8, float(variant * 19), -5)	(8, 7, 6)	matStrata1
1222	Upper darker crag	(1, 5, -1)	(0, 55, 10)	(5, 5, 4)	matStrata2
1223	Lower negative-X outcrop	(-3, 0.8, 2)	(5, -40, 12)	(4, 3, 3)	matStrata2
1224	Small positive-X rubble piece	(3.2, 0.3, 2.2)	(15, 70, 20)	(2.2, 1.6, 2.1)	matStrata1

Every row draws `g_meshRock`, not a cube or sphere. The variant only changes the first piece's Y rotation by 19 degrees per integer variant. It does not select another mesh or alter the other three pieces. A separate per-site rotation in the master scene rotates the whole formation as well. Large nonuniform scales make the repeated mesh less obviously identical, and the different relative positions create a layered cluster. The function does not animate erosion or generate a fresh random rock on each frame; it transforms the mesh already generated during startup.

Rescue Objects and People

Header Integration, Materials, and Landing Base

Original source: lines 1227-1245. The two include directives pull in `arrakis_worm.h` and `arrakis_hud.h` before the rescue-world function and later runtime references. In the organized project these are application headers under `src/`. Including them makes their definitions available to this translation unit; it does not itself draw a worm or show the HUD.

`drawRescueWorld(time)` constructs five materials. `cyan` uses diffuse (0.05, 0.5, 0.55) and emission (0.03, 0.6, 0.65). `amber` uses diffuse (0.9, 0.5, 0.1) and emission (0.6, 0.25, 0.03). `dark` changes diffuse to (0.16, 0.19, 0.19). `cloth` changes diffuse to (0.30, 0.24, 0.17) and specular to (0.03, 0.03, 0.03), leaving shininess 32. `visor` has diffuse (0.08, 0.20, 0.27), specular (0.8, 0.8, 0.8), and shininess 90. Other fields stay at the shared defaults, including `isSand = 0` for all five.

The base parent is an identity matrix translated to `g_mission.base`. Mission reset has already put that position at the intended terrain elevation. This function does not sample the base height again. It draws the following local parts.

Original line	Mesh and base component	T	R	S	Material
1237	Cylinder: broad landing-pad disk	(0, 0.25, 0)	zero	(24, 0.5, 24)	dark
1238	Ring: illuminated landing perimeter	(0, 0.55, 0)	zero	(11, 1, 11)	cyan
1239	Cube: long Z-oriented cross stripe	(0, 0.56, 0)	zero	(1.2, 0.05, 10)	cyan
1240	Cube: long X-oriented cross stripe	(0, 0.56, 0)	zero	(10, 0.05, 1.2)	cyan
1243	Cylinder: perimeter beacon pole	(cos(a) * 13, 2, sin(a) * 13)	zero	(0.2, 4, 0.2)	dark
1244	Sphere: beacon light	(cos(a) * 13, 4.1, sin(a) * 13)	zero	(0.65, 0.65, 0.65)	cyan

The ring scale is literal; it multiplies the ring generator's existing radii rather than specifying a cylinder diameter. The pad disk extends from Y zero to 0.5 relative to the base. The ring and cross are slightly above its top, avoiding exactly coincident surfaces. The pole loop uses integer *i* from zero through three and sets $a = i * \text{half_pi}$, so four beacon pairs occupy the cardinal directions at radius 13. Their cylinder centers are two units high and their heights are four, placing their bottoms at base level; the spheres are just above their tops. Four fixed pad draws plus eight beacon draws give 12 base meshes per invocation. None blinks as a function of *time* in this code.

Released Group Markers and Terrain Alignment

Original source: lines 1246-1261. The group loop uses integer indices from zero up to `g_mission.groups.size() - 1`, with a cast so the container size can be compared to an `int`. It takes a `const` reference to each group. An unreleased group immediately executes `continue`, so there is no ground marker for workers still associated with an unreleased evacuation group.

For a released group, `waiting` starts at zero. An inner crew loop increments it only for a crew member whose group equals the current index and whose state is `Running` or `Waiting`. Other groups and states do not count. If the final count is zero, the group is skipped as well. Thus a released marker remains visible while at least one member is actively running or waiting outside, and disappears after that condition no longer holds. The code bases this visibility on crew states, not on proximity to the camera or aircraft.

The marker position `p` copies `group.center` but replaces its Y value with `getDuneHeight(p.x, p.z) + 0.2`. A translation to that position forms `ring`. The surface normal is sampled at the same X/Z. The code computes `axis = cross((0, 1, 0), normal)` and rotates the ring only if `length(axis) > 0.001`. The angle is `acos(clamp(normal.y, -1, 1))`, and the rotation axis is normalized. The clamp prevents small numeric excursions beyond the legal inverse-cosine range. This rotates the ring's local upward direction toward the terrain normal when there is a usable axis.

Line 1258 draws `g_meshRing` using the tilted root, local T and R zero, S (4.5, 1, 4.5), and `amber`. Lines 1259-1260 deliberately use a fresh translation-only root at `p`, rather than the tilted ring matrix. They draw a dark cylinder at T (4, 2, 0), R zero, S (0.12, 4, 0.12), then an amber sphere at T (4, 4.1, 0), R zero, S (0.5, 0.5, 0.5). The pole and light therefore stay vertical even when the ring follows a slope.

The pole's height is not independently adjusted for the terrain four units to the side: both use the sampled center height through `p`. On sloped ground its bottom can consequently sit differently relative to the nearby surface. If the cross-product axis is too small, the ring remains unrotated; there is no explicit opposite-normal fallback in this group-marker branch. The function uses the actual upward-facing dune normals produced by the terrain helper rather

than adding a general orientation solver.

Visible Crew Bodies, Strides, and Pickup Lift

Original source: lines 1262-1278. The crew loop examines every crew vector entry using its integer index *i*. It only renders Waiting and Running members. Inside, aboard, rescued, or lost crew states do not receive body geometry through this branch. The const reference *c* remains unchanged; rendering works with a copied *crewPosition*.

If *i* equals *g_mission.target* and *g_mission.pickup* > 0, line 1267 raises the copied Y coordinate by $(g_ornPos.y - crewPosition.y - 1.8) * smoothstep(0, 1, pickup)$. At zero eased progress the original height is retained; at full eased progress the crew root reaches *g_ornPos.y* - 1.8. Because the change is made to a copy, it does not overwrite the gameplay crew position. X and Z stay at the member's stored location; this rendering formula only interpolates height.

The crew root is identity translated to that resulting position. *stride* is a degree-valued animation amount: running uses $\sin(time * 11 + i) * 24$, while waiting uses $\sin(time * 2 + i) * 4$. Index *i* adds a phase offset so all people do not swing together. Running uses a faster, wider movement than the small waiting sway. The input *time* comes from the paused-aware simulation clock in the main loop, not directly from the latest GLFW wall clock after that clock is reassigned.

Original line	Mesh and person component	T	R	S	Material
1270	Sphere: torso	(0, 1.05, 0)	zero	(0.55, 0.85, 0.4)	cloth
1271	Sphere: head/helmet	(0, 1.65, 0)	zero	(0.43, 0.46, 0.43)	cloth
1272	Sphere: front visor	(0, 1.67, 0.17)	zero	(0.32, 0.15, 0.10)	visor
1274	Cylinder: leg for each side	(side * 0.14, 0.4, 0)	(side * stride, 0, 0)	(0.17, 0.8, 0.17)	cloth
1275	Cylinder: arm for each side	(side * 0.34, 1.1, 0)	(-side * stride, 0, side * 14)	(0.15, 0.7, 0.15)	cloth
1277	Sphere: overhead locator light	(0, 2.25, 0)	zero	(0.18, 0.18, 0.18)	cyan

The side loop runs exactly twice, for -1 and 1. Leg X rotations have opposite signs on the two sides. Arm X rotations oppose the corresponding leg rotations, while fixed *side * 14* Z rotations splay the arms. These cylinders rotate about their own centers because there is no additional hip or shoulder pivot matrix. There are no separate elbows, knees, hands, feet, or skeletal joints in this function. One visible crew member generates eight draws: torso, head, visor, two legs, two arms, and locator sphere.

No heading rotation is applied to the person root. Regardless of the member's walking direction, the locally positive-Z visor remains oriented according to the same world-axis convention after translation. This is an implementation detail of the primitive figure, not an undocumented facing system. The overhead cyan sphere is attached to the same root, so it rises with the pickup animation.

Winch Rope Orientation and Sandworm Call

Original source: lines 1279-1293. A rope is drawn only when *g_mission.pickup* > 0 and *g_mission.target* >= 0. The branch then indexes *g_mission.crew[target]* directly; it does not independently check that the target is less than the vector size. Valid target management is the mission logic's responsibility.

The initial lower endpoint *end* is the target's stored position plus (0, 1, 0). Its Y is eased by $(g_ornPos.y - end.y - 0.8) * smoothstep(0, 1, pickup)$. This is consistent with the lifted person's root: the person root

tends toward aircraft Y minus 1.8, and adding one puts the rope endpoint at aircraft Y minus 0.8. The upper endpoint start is `g_ornPos - (0, 0.7, 0)`. Aircraft roll and pitch are not used to rotate this attachment offset; it is a world-vertical subtraction from the aircraft position.

`dir = end - start` gives the endpoint displacement, `length = length(dir)` gives the desired rope length, and a translation to `(start + end) * 0.5` puts the cylinder center halfway between them. To align the cylinder's original positive-Y axis, the code crosses world up with `dir / length`. A usable cross product causes a rotation by `acos(clamp(dir.y / length, -1, 1))` about the normalized cross-product axis. If that axis is too small and `dir.y < 0`, it instead rotates by π around X, handling a downward parallel rope. If the displacement points upward with an effectively zero cross product, no rotation is necessary.

Line 1289 draws a cyan cylinder with the assembled rope parent, local T and R zero, S (0.055, length, 0.055). Its thickness is fixed while its axial length tracks the endpoints. The code divides by length before testing the cross-product length and supplies no zero-length guard. It therefore assumes distinct endpoints; this chapter describes the implementation rather than adding a hypothetical correction. The model is a straight cylinder, not a simulated flexible cable or a segmented rope.

After the optional rope, lines 1291-1292 always call `drawSandworm(wormPosition(), wormAttackTime(), time, g_mission.wormYaw, clamp(elapsed / breachAt, 0, 1))`. These arguments supply current terrain-following worm position, time relative to breach, animation time, worm heading, and normalized pursuit progress. The worm renderer itself decides what to show for those phases; the caller does not suppress the call before breach or after mission results. The separate worm chapter explains that renderer's internal meshes. Line 1293 closes `drawRescueWorld`.

Master Scene Traversal

Terrain and Aircraft Visibility

Original source: lines 1295-1316. The banner states that `drawFullScene(curTime)` is used twice per frame, for shadow depth and then the main view. It does not advance gameplay or the wing phase; it constructs the scene from already updated state.

The first object is the terrain. A fresh `matSand` gets diffuse (0.76, 0.49, 0.23), specular (0.25, 0.25, 0.25), shininess 16, and `isSand = 1`, with default zero emission. `drawMeshPrimitive(g_meshTerrain, identity, matSand)` submits the terrain with no extra model translation, rotation, or scaling. The terrain generator has already placed its vertices in scene space.

The aircraft branch runs only if `!g_mission.planeLost`. Its matrix starts as identity translated to `g_ornPos`, then appends Y rotation by `g_ornYaw`, X rotation by `g_ornPitch`, and Z rotation by `g_ornRoll`, each converted from degrees to radians. The composed matrix is passed to the aircraft function along with current phase, roll, pitch, and boost state. The latter two numeric inputs are redundant inside the aircraft function, as noted earlier; the actual bank and pitch are already encoded in this parent matrix. If `planeLost` is true, none of the aircraft's hull, wings, or exhaust draws is submitted here.

Harvester Terrain Slope and Swallowing Transform

Original source: lines 1317-1333. The harvester is rendered only while `wormAttackTime() < 12`. Because attack time is mission elapsed time minus breach time, this includes the entire negative pre-breach interval as well as the first twelve seconds of attack. At exactly 12, this branch stops drawing it.

Its base height `hy` is the dune height at `(g_harvX, g_harvZ)`. `sink = smoothstep(6, 12, attackTime)` stays zero until attack second six, eases upward between six and twelve, and reaches one at twelve. The root translation uses `height hy - sink * 20`, sinking the machinery by as much as twenty units while it is still being drawn. It then receives the harvester's Y heading in degrees.

Slope alignment is expressed in the vehicle's heading-relative axes. `hnorm` is the sampled dune normal, `forward` is the horizontal forward vector from `harvesterForward(harvesterYaw)`, and `right = cross(forward, (0, 1, 0))`. The X rotation is `atan2(-dot(hnorm, forward), hnorm.y)` and the Z rotation is `atan2(-dot(hnorm,`

`right), hnorm.y)`. Unlike the heading, these inverse-trigonometric angles are already radians and are passed directly to GLM. Using the projections onto forward and right makes the apparent uphill/downhill tilt depend on the crawler's heading instead of blindly applying world-X/world-Z slopes.

An additional X rotation of $\text{sink} * 0.8$ radians supplies the swallowing tilt. It is not 0.8 degrees: GLM receives it directly. The final harvester matrix includes translation, yaw, terrain pitch, terrain roll, and this extra pitch in that append order. `drawSpiceHarvester` receives it together with `g_mission.harvesterTravel`, which animates tracks and drum according to accumulated travel. The master draw does not itself advance that travel or move the crawler's route.

Tank Instances, Eight Rock Sites, and Rescue World

Original source: lines 1334-1354. Every tank in `g_tanks` is considered separately. Its branch uses `if (wormAttackTime() > 12) continue`, which differs from the harvester's `strict < 12` draw condition. A tank still draws at exactly attack second twelve; the harvester does not. At later times every tank iteration skips the remaining body. This skips rendering, not deletion of tank entries from the vector.

For a drawn tank, terrain height is recomputed from the tank's X/Z coordinates. The stored `tank.pos.y` is not used. The root becomes translation to `(tank.pos.x, terrainHeight, tank.pos.z)`, followed by Y rotation from `tank.yaw` degrees and uniform scale `(tank.scale, tank.scale, tank.scale)`. The vessel function then supplies all its local geometry. No dune-normal tilt is applied to the tanks here; their roots remain upright even on a slope. The comment's description of tanks deployed behind the harvester does not make this loop continuously relocate them with the crawler. Their positions come from the instance data maintained elsewhere.

The rocks use a fixed eight-iteration loop. Each `g_rockSites[i]` is read as a two-dimensional X/Z site: its `.x` becomes `rx` and its `.y` becomes `rz`. The world Y value is the dune height minus 0.5, partially embedding each formation's root. A site root is translated there and rotated around Y by $i * 45$ degrees. The same integer `i` is passed as the formation variant, giving its first rock an additional local $i * 19$ Y rotation. Eight sites times four rock meshes yields 32 rock draws per scene traversal.

Finally the function calls `drawRescueWorld(curTime)`, which adds the base, active group markers, visible people, optional rope, and worm. Rescue markers are not rendered as a separate screen overlay here; they are world-space meshes and therefore participate in both full-scene passes. The HUD is drawn later, outside `drawFullScene`, only in the main framebuffer sequence. The closing brace completes the shared scene traversal.

GLFW Input Callbacks

Framebuffer Resize and Mouse Recentering

Original source: lines 1356-1374. The callbacks section begins with a framebuffer-size function taking an unnamed window pointer and new framebuffer width/height. Only when both `w > 0` and `h > 0` does it update `g_scrW`, `g_scrH`, and the viewport to `(0, 0, w, h)`. Zero-size dimensions, such as can occur while minimizing, are ignored rather than stored. This keeps the last positive dimensions available to projection and screenshot code. Framebuffer dimensions are physical rendering pixels and can differ from the logical window dimensions used for cursor movement.

`centerMouse(win)` obtains logical window width and height using `glfwGetWindowSize`. It immediately zeros `g_mouseHover` and `g_mouseTurnRate`, then places the cursor at `(width * 0.5, height * 0.5)` using floating-point halves. This resets both the instantaneous hover displacement and the smoothed turning state; it is more than a visual mouse reposition. It does not resize the framebuffer, clear held keyboard keys, or alter the aircraft heading.

Cursor Motion Eligibility and Coordinate Space

Original source: lines 1375-1387. Cursor motion is accepted only when the mission is `Flying`, is not paused, and the window reports focus. If any of those conditions fails, both mouse-hover and turn-rate globals are set to zero and the callback returns immediately. Thus moving the mouse at the title screen, during results, while paused, or without focus cannot keep injecting steering through this callback.

For accepted motion, the code queries the current logical window dimensions and calls `setMouseHover(x, y, width, height)`. It deliberately does not use `g_scrW/g_scrH`, since cursor coordinates are logical window pixels. The helper validates dimensions and coordinates, converts them to centered hover values, and applies its dead zone; that helper is documented with the mission code. This callback itself neither recenters the mouse after every movement nor hides or locks the pointer. Its model is cursor position relative to the window center, not accumulated relative mouse displacement.

Key State and Immediate Actions

Original source: lines 1388-1427. `key_callback` names the window, key, and action arguments but leaves scan code and modifier flags unnamed because it does not inspect them. For valid integer key indices $0 \leq \text{key} < 1024$, press sets `g_keys[key]` true and release sets it false. Repeat is not treated as another press in those statements, so it neither toggles features nor changes the held state. A held key remains true from its original press until release or the focus-loss clearing callback.

The rest of the function uses independent `if` statements for the following immediate key actions. Every action below requires `GLFW_PRESS`; holding a key does not repeatedly toggle it through GLFW's repeat action.

Key	Exact callback behavior	Phase restriction
Escape	Sets the window should-close flag to true.	None.
F	Flips <code>g_wireframe</code> ; selects <code>GL_LINE</code> or <code>GL_FILL</code> for front and back polygon faces.	None.
C	Advances <code>g_camMode</code> with <code>(g_camMode + 1) % 3</code> .	None.
Enter	From Title calls <code>resetMission(true)</code> ; from Debrief calls <code>resetMission(true, true)</code> ; then calls <code>centerMouse</code> regardless.	Reset depends on phase; recentring does not.
R	Calls <code>resetMission(true)</code> and <code>centerMouse</code> .	None.
M	Calls <code>g_audio.toggleMute()</code> .	None.
P	Flips <code>g_mission.paused</code> and recenters the mouse.	Only Flying.
F11	Toggles the fullscreen flag, switches window monitor mode, then recenters.	None.

Escape requests termination of the loop but does not immediately delete resources inside the callback. F changes rasterization mode for subsequent geometry, while the HUD later explicitly forces filled polygons for its own draw. C's three values are chase, close view, and overhead in the helper; the word cockpit in the source label does not insert an interior cockpit mesh. Enter while already Flying only centers the mouse, because neither reset condition matches. Enter from Debrief passes the second `true` argument to advance the mission wave, while R retries using the reset function's default second argument. The callback does not apply modifier requirements such as Ctrl or Alt.

F11 always fetches the primary monitor and its current video mode. When entering fullscreen, it attaches the existing window to that monitor at position `(0, 0)`, using the mode's width, height, and refresh rate. When leaving fullscreen, it detaches from any monitor and requests a window at `(100, 100)` with size `1280 x 720` and refresh-rate argument zero. It does not save and restore the prior arbitrary window position or size. This branch assumes that primary-monitor and video-mode queries return usable values; it includes no null check. Resizing and cursor-centering can also trigger the separately registered GLFW callbacks. The function's final brace ends input handling without any mission update call.

Screenshot File Encoding

Readback Buffer and Little-Endian Writer

Original source: lines 1429-1439. The main-entry section banner precedes `captureScreenshot(path)`. The function allocates `g_scrW * g_scrH * 4` unsigned bytes. The width is converted to `size_t` before multiplication, avoiding a purely signed intermediate for the full allocation expression under the normal positive-dimension invariant.

`glReadPixels(0, 0, width, height, GL_BGRA, GL_UNSIGNED_BYTE, pixels.data())` reads the entire current framebuffer region starting at its lower-left corner. Each pixel contributes blue, green, red, and alpha bytes. The function does not choose a new framebuffer or call `glReadBuffer`; it relies on the rendering state at the call site, where the main framebuffer has been rendered and buffer swapping has not yet occurred. It also does not explicitly set pixel pack state. At four bytes per pixel, every row length is a multiple of four, compatible with the usual default pack alignment.

It opens the requested path as a binary `std::ofstream`. If opening fails, it returns false immediately. Readback has already taken place before this check. The function does not create missing parent directories or infer an image format from the filename extension. Its local `word(value, bytes)` lambda emits bytes least-significant bytes of a `uint32_t` in order, using right shifts by `i * 8`, a mask of 255, and `out.put`. That implements little-endian integer serialization independently of directly writing a C++ header struct with platform padding.

BMP Header, Row Direction, and Result

Original source: lines 1440-1446. The output is a 32-bit uncompressed BMP. The first two bytes are literal B and M. The following fields are written in this exact order.

Header field	Bytes	Assigned value and meaning
File signature	2	BM, identifying a Windows bitmap file.
Total file size	4	<code>54 + pixels.size()</code> , cast to <code>uint32_t</code> .
Reserved fields	4 combined	Zero for both reserved 16-bit fields.
Pixel-data offset	4	54, immediately after the two headers.
DIB header size	4	40, the <code>BITMAPINFOHEADER</code> layout.
Width	4	<code>g_scrW</code> .
Height	4	Positive <code>g_scrH</code> , specifying bottom-up storage.
Planes	2	1.
Bits per pixel	2	32.
Compression	4	0, uncompressed <code>BI_RGB</code> .
Pixel-data byte count	4	<code>pixels.size()</code> , cast to <code>uint32_t</code> .
Horizontal resolution	4	Zero.
Vertical resolution	4	Zero.
Palette colors used	4	Zero.
Important palette colors	4	Zero.

OpenGL supplies the bottom framebuffer row first, and positive BMP height also expects bottom-up rows, so no explicit vertical flip is needed. Four bytes per pixel make rows naturally aligned for BMP storage without added row padding. The BGRA byte order matches the pixel layout written here. `BI_RGB` at 32 bits stores the fourth byte, but this routine

does not add alpha bit masks or promise that every bitmap viewer treats that byte as usable transparency.

Line 1444 writes the entire byte vector as raw data after the header. It casts the pointer to `const char*` and the length to `std::streamsize` to match the stream API. `return out.good()` reports the stream's status after these writes; the local stream closes on scope exit. The function does not test for an OpenGL readback error itself or perform image-content validation. Sizes are serialized into 32-bit fields without a separate oversized-image guard. It is a screenshot of what was rendered, including the HUD when called from the frame loop, not a scene-only render or a PDF export.

Application Startup

Command-Line Dispatch and GLFW Initialization

Original source: lines 1448-1459. `main(argc, argv)` first checks whether `argv[1]` is exactly `--test-game`. If so, it directly returns `runMissionTests()`, bypassing GLFW initialization, window creation, GLAD loading, audio initialization, and the render loop. The tests are implemented in `tests/arrakis_tests.h` in the organized project. This chapter does not duplicate their individual assertions.

Otherwise it sets four booleans by comparing only the first argument. `smokeTest` corresponds to `--smoke-test`, `breachTest` to `--smoke-breach`, `mouseTest` to `--smoke-mouse`, and `pursuitTest` to `--smoke-pursuit`. `renderTest` is their logical OR. Since each equality tests the same single string, normally only one mode can be selected. There is no general command-line parser, combined-flag scan, help option, or validation of unrecognized arguments. With an unrecognized first argument, the normal interactive path is followed. An optional second argument is considered later only as the screenshot path for render-test modes; additional arguments are not used in this code.

First argument	Startup/runtime specialization
<code>--test-game</code>	Runs mission tests and returns their result without graphics startup.
<code>--smoke-test</code>	Starts a flying mission and renders with fixed simulation steps for the bounded test run.
<code>--smoke-breach</code>	Additionally advances mission state to seven seconds after its breach time and uses the breach camera.
<code>--smoke-mouse</code>	Supplies synthetic horizontal mouse positions, holds W, cycles camera modes, and checks camera heading.
<code>--smoke-pursuit</code>	Advances mission state to 110 seconds and uses a wider harvester/worm pursuit camera.
No recognized first argument	Starts in the ordinary title-screen path.

If `glfwInit()` fails, the program writes `Failed to initialize GLFW` to standard error and returns `-1`. No GLFW window or OpenGL resources have been created by the following startup sequence yet. This failure is separate from the later render-test failure status, which uses exit code one.

Context Hints, Monitor Information, and Window Fallback

Original source: lines 1460-1485. GLFW hints request OpenGL version 3.3 with a core profile. The program gets the primary monitor and its current video mode, then copies that mode's red, green, and blue bit depths and refresh rate into window hints. It also requests four multisample samples. These are requested capabilities; GLFW and the underlying platform determine the actual context/window characteristics. No explicit alpha-bit, depth-bit, stencil-bit, or hidden-window hint is set in this range.

Although the monitor's properties are queried, the first `glfwCreateWindow` uses `nullptr` for its monitor argument, so startup is windowed. It uses the current global dimensions, initially 1280 x 720, with the title `ARRAKIS | Harvester Down - Desert Rescue`, and `nullptr` for the shared-context argument. The comment explicitly favors desktop accessibility and leaves fullscreen switching to F11. Render smoke tests also use this windowed creation path rather

than a special headless or hidden window.

If creation returns null, the program prints `Window creation failed, falling back to windowed mode...`, clears `g_isFullscreen`, sets the dimensions to 1280 x 720, and attempts another window titled `ARRAKIS`, again with no monitor and no shared context. The fallback message does not mean the first attempt was fullscreen: both calls are windowed in the inspected implementation. The second attempt changes the title and resets the dimensions but does not clear the previously requested context, color, refresh, or sample hints. If it also fails, GLFW is terminated and `main` returns -1.

Primary-monitor and mode pointers are dereferenced without a null guard in this startup range, just as they are in F11 handling. This is an assumption of the actual code, not a fallback for a machine with no available monitor.

Context Activation, Callback Registration, and Focus Loss

Original source: lines 1486-1505. The successful window's OpenGL context is made current. Its framebuffer size is read into `g_scrW` and `g_scrH`, so rendering dimensions reflect actual framebuffer pixels rather than only the requested logical window size. The named framebuffer-size, key, and cursor-position callbacks described above are registered next.

Three additional callbacks are inline lambdas. The cursor-enter callback ignores both its window pointer and the entered/left flag and always zeros `g_mouseHover` and `g_mouseTurnRate`. It therefore clears steering on either entry or exit. The window-size callback ignores the supplied new size arguments and calls `centerMouse(win)`, which queries the current logical size itself. The focus callback only acts when `focused` is false: it clears every element of the 1024-entry key array using `std::fill`, zeros the two mouse steering values, and sets mission pause true if the mission is Flying.

On focus regain, that callback has no corresponding resume branch. A flying mission remains paused until another action, such as P, changes the flag; a render test later forces it false on each normal frame. Clearing held keys avoids a key remaining logically down after a release event occurs outside focus. The focus callback does not close the window, reset the mission, mute the audio flag, or save a special focus-loss result state.

`glfwSwapInterval(1)` requests vertical synchronization against the current context. It governs swap timing, not the physics step size or the number of mission substeps. GLAD entry points are loaded only afterward. GLFW callback registration does not itself invoke the OpenGL viewport callback here; event processing is deferred to the later loop.

GLAD, Audio Initialization, Diagnostic Banner, and GL State

Original source: lines 1506-1526. The GLAD loader is called with GLFW's procedure-address function cast to `GLADloadproc`. If it fails, the program prints `Failed to initialize GLAD`, calls `glfwTerminate`, and returns -1. This path does not reach the final normal resource cleanup block. GLFW termination handles GLFW-owned window lifetime, but no application geometry or shader resources have yet been created by the later lines.

`g_audio.init()` runs after GLAD succeeds. Its boolean return value is not checked by `main`, so an audio initialization failure is not itself fatal to graphics startup. The audio subsystem records whether it initialized and supports its silent-mode path; its implementation and asset lookup are covered separately. Organizing the audio files under `assets/audio/` concerns that subsystem's file locations, not extra arguments passed here.

Six output statements print separator lines, the game title, renderer string from `glGetString(GL_RENDERER)`, OpenGL version from `glGetString(GL_VERSION)`, and current framebuffer resolution. These diagnostics describe the active driver and framebuffer, not a benchmark. The program does not inspect these strings to select a different renderer or shader variant.

Initial OpenGL state enables depth testing and multisampling, chooses `GL_LEQUAL` for depth comparison, enables face culling, and selects back-face culling. Less-or-equal allows a fragment at exactly the stored depth to pass. Individual render phases temporarily change selected state later; they do not reinitialize all possible OpenGL settings every frame. Blend remains unenabled by this initialization block until the particle stage explicitly enables it.

Procedural Meshes and Shader Programs

Original source: lines 1527-1543. Startup generates and uploads the reusable scene meshes in a fixed order. `createCube()` creates the box used for structural details; `createCylinder(24)` requests 24 radial slices; `createSphere(16, 24)` uses 16 latitude and 24 longitude subdivisions; and `createWingBlade()` creates the tapered aerofoil reused by all aircraft wings. `createDuneTerrain(260, 260, 900.0)` builds the broad terrain using those grid and extent arguments. The actual startup values here take precedence over looser descriptions elsewhere in source comments.

`createQuad()` supplies the billboard mesh for particle rendering. `createRing()` supplies landing and evacuation markers, and `createErodedRock()` supplies rock formations. `initSandwormMeshes()` initializes the worm renderer's own resources. Each result is stored in a corresponding global mesh so multiple objects and frames can reuse it. These calls happen once during startup rather than regenerating primitives inside every `drawPart`.

Four `buildProgram` calls compile/link the scene, shadow, particle, and sky programs from their respective vertex and fragment shader strings: `SCENE_VERT/SCENE_FRAG`, `SHADOW_VERT/SHADOW_FRAG`, `PARTICLE_VERT/PARTICLE_FRAG`, and `SKY_VERT/SKY_FRAG`. The resulting IDs are stored in `g_progScene`, `g_progShadow`, `g_progParticle`, and `g_progSky`. The preceding rendering chapter explains the individual shader expressions and mesh-generation loops; this range connects those resources to the application's lifecycle.

Shadow/Sky/HUD Resources and Particle Instance Attributes

Original source: lines 1544-1563. `setupShadowFramebuffer()` creates the depth-rendering target, `setupSkyVAO()` prepares the sky's screen-filling triangle resources, and `initRescueHud()` prepares HUD resources. Immediately afterward, startup checks both `g_shaderOkay` and the HUD resource program ID. If any earlier shader build reported failure or the HUD program is zero, it destroys the window, terminates GLFW, and returns 1.

This early failure path does not run the comprehensive cleanup at the bottom of `main`: it has no explicit calls here to delete the already created meshes/programs or shut down audio. Context destruction and process termination end their usable lifetime, but the code's explicit successful-path deletion sequence is not executed. The condition is also not a full audit of every OpenGL object or framebuffer; it checks the displayed shader status and HUD program specifically.

`initParticles()` initializes the CPU particle collection. The program generates `g_particleInstanceVBO`, binds the quad VAO, and binds that new buffer as `GL_ARRAY_BUFFER`. It initially allocates `MAX_PARTICLES * sizeof(ParticleInstance)` bytes with null data and `GL_STREAM_DRAW`. The earlier constant is `MAX_PARTICLES = 2400`. Each `ParticleInstance` contains two `glm::vec4` fields, `posSize` and `colorAlpha`.

The two-iteration loop enables vertex attribute locations 3 and 4. Both attributes contain four `GL_FLOAT` values, are not normalized, use `sizeof(ParticleInstance)` as stride, and have offsets 0 and `sizeof(glm::vec4)` respectively. The offset is passed using a `reinterpret_cast<void*>`, which OpenGL interprets as a byte offset into the currently bound VBO rather than a CPU pointer to read. Setting each divisor to one makes its value advance once per drawn instance rather than once per quad vertex. The quad's existing per-vertex attributes remain attached to the same VAO.

After unbinding the VAO, `g_particleInstances.reserve(MAX_PARTICLES)` reserves CPU vector capacity without filling it. `resetMission(renderTest)` initializes the world: normal interactive startup receives false and opens at Title; any recognized render-test mode receives true and starts Flying. `centerMouse(g_window)` then clears steering and places the pointer at the logical center. This order ensures reset mission state exists before the camera and timing state are initialized.

Render-Test Fast-Forward and Environment Constants

Original source: lines 1564-1578. Breach and pursuit modes advance the mission before ordinary frames begin. `targetTime` is `g_mission.breachAt + 7` for breach mode and `110.0` for pursuit mode. `steps = int(ceil(targetTime * 120))`, and the loop calls `updateMission(targetTime / steps)` exactly that many times. This supplies roughly 120 simulation updates per target second instead of passing the entire interval as one unstable update.

It then places the aircraft at `harvesterPosition() + (35, 16, 40)` and sets `g_mission.altitude = 16`. The direct position is a world offset from the harvester; the altitude field records a separate intended terrain-following height. This range does not reset velocity, yaw, or all remaining mission fields after fast-forward. It also does not explicitly assign `elapsed = targetTime`: elapsed state is whatever the repeated float-valued mission updates produced, subject to their phase checks and floating-point accumulation. Other render-test modes do not execute this pre-advance block.

Lighting constants are local to main: `sunDir` is the normalized vector `(-0.35, 0.12, -1.0)`, `sunColor` is `(1.15, 1.04, 0.85)`, `ambientColor` is `(0.34, 0.38, 0.44)`, `fogColor` is `(0.90, 0.74, 0.47)`, and `fogDensity` is `0.0022`. Normalizing the direction keeps subsequent dot products and light-camera placement independent of the vector's original magnitude. Sun color values above one allow a bright warm contribution; these constants are not clamped by main. Fog supplies both the framebuffer clear color and the scene shader's atmospheric color. No day/night clock or runtime light-color change appears here.

Initial Clocks, Camera Damping State, and Test Counters

Original source: lines 1579-1593. `prevTime` records the current GLFW time as a float. `camPosSmoothed` starts at aircraft position plus `(0, 26, 42)`, and `camTargetSmoothed` starts at the aircraft itself. This initial position is a world-space offset, not yet the helper's heading-relative chase placement. The first normal camera update below replaces X/Z placement with the actual current offset while smoothing height and target.

`simulationTime` starts at `g_mission.elapsed`, including any pre-advanced test state. It is a separate local animation clock, not an alias of the mission timer. `fps` starts at 60, `frameCount` at zero, and `cameraRevision` copies `g_missionRevision`. `renderFailed` starts false. `smokeStarted` records a fresh double-precision GLFW timestamp after resource setup and any fast-forward work; therefore the printed render-test duration later excludes those earlier initialization costs.

The banner at lines 1591-1593 introduces the main loop. There is no second thread or scheduler in this section: event handling, simulation stepping, audio parameter updates, both geometry passes, particles, and the HUD are driven sequentially by the loop.

Frame Timing and Simulation

Window Lifetime, Minimize Wait, and Delta Clamp

Original source: lines 1594-1606. The loop condition continues while GLFW's should-close flag is false. On an iconified/minimized window, it calls `glfwWaitEvents()`, updates `prevTime` to the current time after that wait, and immediately continues. That iteration performs no ordinary polling, mission update, audio update, rendering, buffer swap, screenshot, or render-test frame-count increment. Resetting `prevTime` avoids counting the entire minimized wait as the next physics interval.

On a normal iteration, `curTime` initially means GLFW wall time, `dt = curTime - prevTime`, and `prevTime` is updated before events are polled. If `dt > 0.1`, it is reduced to `0.1`; there is no corresponding lower clamp in these lines. `realDt` copies this already capped value. Thus the FPS estimate later uses the capped interval, not the uncapped duration of an unusually slow frame. The clamp bounds simulation work and jump size at low rendering rates but deliberately discards excess elapsed wall time rather than accumulating a catch-up backlog.

`glfwPollEvents()` delivers callbacks near the beginning of a normal frame. A callback can reset the mission, pause it, change rendering mode, or request close before subsequent operations. Setting should-close during polling does not instantly jump out of this body: the existing frame still continues unless other control flow changes it, and the next loop-condition check ends the run.

Fixed Render-Test Input and FPS Smoothing

Original source: lines 1607-1618. Every render-test frame replaces `dt` with `1 / 60` and forces `g_mission.paused = false`. It clears `g_mouseHover` but does not clear all keys or explicitly zero `g_mouseTurnRate` at that point. The synthetic test time is independent of actual wall time and VSync timing; `realDt` still retains the earlier measured, capped interval for FPS display.

Mouse mode queries logical window dimensions and calls `setMouseHover` at 85 percent of the width for `frameCount < 60`, or 15 percent otherwise, always halfway down the window. Frames zero through 59 therefore steer from the right side; frames 60 through 119 use the left side. It sets the `W` key state true and selects `g_camMode = (frameCount / 40) % 3`, testing mode zero for the first 40 frames, one for the next 40, and two for the last 40. No synthetic release of `W` is needed after completion because the test closes the application; the code does not restore prior input state mid-run.

The FPS value is updated with `mix(fps, 1 / max(realDt, 0.0001), 0.03)`. Only three percent of the new instantaneous estimate is incorporated each frame, giving a damped display. The minimum denominator protects against division by zero and caps the instantaneous estimate at 10000. Because `realDt` has already been capped above at `0.1`, an extremely long frame supplies an estimate of ten rather than its truly lower uncapped FPS. This statistic is display telemetry, not a pass/fail performance threshold.

Bounded Mission Substeps, Debrief Time, and Particle Updates

Original source: lines 1619-1630. Simulation work runs only when the mission is not paused. It computes `steps = max(1, int(ceil(dt / (1 / 120))))`, then invokes `updateMission(dt / steps)` repeatedly. At the normal render-test `dt = 1 / 60`, this is approximately two substeps per rendered frame. At the maximum `0.1` interval it is approximately twelve. The `max(1, . . .)` prevents a zero-iteration loop for a zero interval. Every substep receives an equal fraction of the frame interval.

The mission helper itself rejects updates outside Flying or while paused, so entering this outer block does not force title or debrief gameplay to advance. After the substep loop, however, if the phase is Debrief, the code adds the full `dt` to `g_mission.elapsed`. This allows breach/swallow/retreat visuals to continue behind the results UI. If a substep changes the phase to Debrief during the frame, the same post-loop addition still occurs; it is not prorated to only the leftover fraction of that frame.

The separate `simulationTime` always advances by `dt` inside the unpaused block, even on Title or Debrief. On Title, `g_wingPhase` additionally advances by `18 * dt`, keeping the preview aircraft's wings moving despite the mission helper not running flight gameplay. During normal flight the mission helper manages the wing phase. `updateParticles(dt, g_orbPos, harvesterPosition())` runs once per frame, not once per mission substep, with current aircraft and crawler positions.

Finally `curTime = simulationTime` repurposes the local variable. All later rendering in that frame uses the simulation animation clock, not the initial GLFW timestamp. Pausing freezes this clock, wing/title advancement, and particles, while the later render and audio call paths still execute. Resetting the mission does not reassign this local clock after its startup initialization, so visual animation phase can continue across retries even as mission elapsed resets. Minimization skips the block entirely rather than merely setting its `dt` to zero.

Camera System

Mission Revision and Keyboard Elevation

Original source: lines 1631-1643. The camera section compares its saved revision with `g_missionRevision`. Mission resets increment that global. On a mismatch, it updates the saved value, puts `camPosSmoothed` at aircraft position plus `(0, 14, 38)`, and sets `camTargetSmoothed` directly to the aircraft. This prevents the new mission camera target from easing all the way from an obsolete world location. It is a different initial height/offset from the first startup `(0, 26, 42)` values.

If not paused, Up raises `g_camOrbitPitch` by `40 * dt` degrees but caps it at 45; Down lowers it by the same rate but floors it at -10. These are separate ordered statements, not an `else if`. If both keys are held, both adjustments

run, and the bounds can affect the outcome near the limits. This block changes the camera's elevation-control variable, not the aircraft's physical pitch. While paused, held arrow keys do not advance that variable here.

Normal and Test Camera Targets

Original source: lines 1644-1654. The default target is aircraft position. `flightCameraOffset(g_camMode)` computes the current heading-relative offset, and the default desired position is aircraft plus that offset. The helper's actual conventions are relevant because source labels call mode one cockpit even though its implementation is a close third-person offset.

The helper forms behind = `-flightForward().Mode two is behind * 26 + (0, 100, 0)`. Other modes use a pitch angle derived from `clamp(12 - mouseHover.y * 22 + g_camOrbitPitch, 6, 65)` degrees. Mode one uses distance 20 and an additional 2.2 vertical offset; mode zero uses distance 40 with no such addition. The horizontal distance is `distance * cos(pitch)`, and the height is `distance * sin(pitch)` plus the mode-one addition. All three remain behind the aircraft in X/Z rather than becoming an actual first-person eye inside its hull.

Breach mode overrides the target to `harvesterPosition() + (0, 14, 0)` and desired position to `harvesterPosition() + (65, 48, 80)`. Pursuit mode, in an `else if`, aims at the midpoint of harvester and worm plus `(0, 6, 0)` and places its desired eye at that target plus `(65, 30, 155)`. If no specialized test camera is active, the helper's ordinary aircraft target and offset remain. The test overrides change desired position and target but do not overwrite the separately computed `camOffset`; the next stage handles their X/Z values explicitly.

Terrain Clearance and Heading-Preserving Smoothing

Original source: lines 1655-1669. First, desired camera Y is raised if necessary to at least `getDuneHeight(desiredX, desiredZ) + 1.5`. The target is not terrain-clamped by this statement. Camera height then eases toward desired height with coefficient `1 - exp(-9 * dt)`. Target position eases toward `camTarget` with the faster coefficient `1 - exp(-12 * dt)`.

Camera X and Z are not independently eased from their previous world positions. They are assigned `camTargetSmoothed.x + camOffset.x` and `camTargetSmoothed.z + camOffset.z`. Because the horizontal offset is exactly behind the aircraft's current heading, this preserves the view direction's horizontal alignment even when the target itself lags slightly in translation. Independently smoothing old world X/Z positions could leave the aircraft visibly side-on during turns; the source comments explain why this alternative is not used.

For breach or pursuit modes, X and Z are then assigned directly from `camDesiredPos` instead. Their height still uses the easing calculation, and their target still eases. A second terrain safety check clamps the final smoothed eye Y to at least terrain height at its actual X/Z plus 2. This second threshold is higher than the earlier 1.5 desired-position threshold and applies after horizontal reassignment, so it protects the actual rendered eye rather than only the requested one.

The smoothing calculations occur even while paused because the outer pause check only surrounds the keyboard elevation change, not this matrix preparation. With a positive measured `dt`, a paused camera can finish settling toward a stationary target. No terrain-based camera-target obstruction test, wall collision, or automatic zoom is implemented in this range.

Mouse-Test Heading Check and View/Projection Matrices

Original source: lines 1670-1682. In mouse smoke mode, `viewForward = camTargetSmoothed - camPosSmoothed` has its Y component set to zero. The code normalizes that horizontal direction and compares its dot product with `flightForward()` against 0.9999. A smaller value prints `Camera heading diverged from aircraft`, sets `renderFailed`, and requests window close. It does not immediately break the frame body, so rendering and final accounting can still continue for that iteration. There is no zero-vector normalization guard in this test, although the ordinary camera helper supplies a nonzero behind offset for its three modes.

`glm::lookAt(camPosSmoothed, camTargetSmoothed, (0, 1, 0))` creates the viewing matrix with world Y as up. The aspect ratio is `framebuffer width divided by framebuffer height as floats`. The projection is perspective with a 58-degree vertical field of view, that aspect ratio, near distance 0.4, and far distance 1200. These values are fixed in

the frame loop; none is changed by C or fullscreen except that a framebuffer resize changes aspect. The positive-size framebuffer callback ordinarily preserves a usable denominator during minimization, which is also skipped earlier in the loop.

Spatial Audio Handoff

All Eighteen Update Arguments

Original source: lines 1683-1704. The runtime first asks `nearestCrewPosition()` for a sound-interest position, then measures its horizontal distance from `g_ornPos`. The mission helper considers Running and Waiting crew and falls back to harvester position when no suitable closer candidate is found. That fallback means the returned point need not be a real crew member, and the caller sends it anyway. Distance is horizontal X/Z distance rather than a full camera-to-source or three-dimensional aircraft-to-person distance.

The single `g_audio.update` call occurs after camera calculation and before shadow rendering. Its arguments appear in the following exact order.

Position	Supplied expression	Meaning at the call boundary
1	<code>dt</code>	Current frame update interval; fixed to 1/60 for render tests.
2	<code>camPosSmoothed</code>	Listener eye position from the final terrain-safe camera.
3	<code>camTargetSmoothed</code>	Listener look target.
4	<code>g_ornPos</code>	Aircraft sound-source position.
5	<code>g_ornSpeed</code>	Current flight speed input.
6	<code>g_isBoosting</code>	Current boost boolean.
7	<code>harvesterPosition()</code>	Current harvester sound-source position.
8	<code>wormPosition()</code>	Current worm sound-source position.
9	<code>wormGap()</code>	Harvester-to-worm pursuit gap supplied by mission logic.
10	<code>wormAttackTime()</code>	Elapsed time relative to breach, negative before breach.
11	<code>g_mission.rescued</code>	Delivered-rescue count.
12	<code>g_mission.aboard</code>	Current onboard crew count.
13	<code>g_mission.pickup</code>	Pickup/winch progress.
14	<code>nearestCrewAudio</code>	Nearest eligible crew point or helper fallback.
15	<code>nearestCrewDistAudio</code>	Horizontal aircraft distance to that point.
16	<code>g_mission.base</code>	Base position for delivery-related audio.
17	<code>phase == Flying</code>	Whether gameplay is currently Flying.
18	<code>g_mission.paused</code>	Pause state, passed rather than suppressing the call.

Camera position and target make listener orientation match what the user sees. Mission counters and progress let the subsystem recognize transitions rather than merely play a uniform ambient loop. `wormGap()` is not the listener's distance to the worm; the separate worm position enables spatial positioning. The caller does not pass mute because the audio object already owns its muted field, which M toggles.

This call still happens on Title, Debrief, and paused rendered frames; `isFlying` and `isPaused` convey the correct phase. The audio implementation can return early when uninitialized or silence its master engine while paused/muted. Minimized frames do not reach it because the iconified branch continues earlier. The main source does not manually start every sound here or check an audio-update return status. The audio chapter describes volumes, pitch changes, one-shot detection, and asset loading in `src/arrakis_audio.h` rather than attributing those internal actions to this call site.

Shadow Rendering Pass

Depth Target and Player-Centered Light Camera

Original source: lines 1705-1721. The first render pass sets `g_isShadowPass = true`, changes the viewport to `SHADOW_RES x SHADOW_RES` (2048 x 2048 from the earlier constant), binds `g_shadowFBO`, and clears its depth buffer. It does not clear a color buffer because this target is used for shadow depth. The pass flag makes the shared mesh helper choose shadow-specific model/surface uniforms.

The shadow camera follows the aircraft's X/Z area, even in breach or pursuit smoke modes where the view camera may look elsewhere. `shadowCenter` starts at aircraft position but replaces Y with the dune height at the aircraft X/Z, so the light aims at ground under the player rather than the aircraft's altitude. `shadowBoxSize` is 90. The orthographic light projection spans `[-90, 90]` in both X and Y, with near/far distances 2 and 320, giving a 180-unit-wide square coverage area in light-view coordinates.

The light eye is `shadowCenter + sunDir * 120`. A look-at matrix points it at `shadowCenter` using world Y up. `lightSpaceMatrix = lightProj * lightView` transforms a world-space position into the light's projected space. There is no perspective narrowing or per-object light camera, and no second cascade for distant terrain in this range. Following the player prioritizes shadow detail near flight and rescue action rather than uniformly covering the entire 900-unit terrain extent.

Shadow Uniforms, Collapse Synchronization, and Bias

Original source: lines 1722-1736. The shadow shader becomes current. Its `lightSpaceMatrix` uniform receives one matrix, without transpose, using `glm::value_ptr`. The program then stores `wormCenter = wormPosition()` and `collapse = smoothstep(7, 14, wormAttackTime())`, sending those to shadow uniforms `wormCenter` and `collapse`.

The collapse scalar is zero through attack second seven, eases to one between seven and fourteen, and remains one afterward. It differs from the harvester sink interval of six to twelve. The preceding shader implementation uses these values for the affected terrain treatment. Computing them once here and reusing them in the scene pass keeps the shadow geometry's deformation parameters synchronized with visible terrain. `wormCenter` is a saved frame value used later for HUD coordinates as well.

The shader's terrain lowering applies only to `isSand == 1`. Rock materials marked 2 do not receive that terrain displacement. The scene shader lowers affected terrain vertices by `collapse * (1 - smoothstep(5, 48, distanceFromWormXZ)) * 13`, but the CPU `getDuneHeight` queries used for object placement, camera clearance, and HUD altitude still describe the original dune surface. The shader also retains the uploaded normal rather than recomputing a crater normal. Consequently the synchronized color/depth crater is a visual deformation, not a replacement CPU terrain or a general physical ground-collapse model. The separately sinking harvester gets its own explicit root transform.

The code enables `GL_POLYGON_OFFSET_FILL` and sets `glPolygonOffset(2.5, 4.0)` before drawing the scene. Polygon offset combines a slope-dependent contribution with a fixed depth-unit contribution, biasing filled depth polygons to reduce self-shadow acne. It does not change each model matrix or shift geometry in world coordinates. The mode is specifically fill-offset; the user-selected line rasterization mode is not forcibly replaced for this pass by these statements.

`drawFullScene(curTime)` submits terrain, any visible aircraft/harvester/tanks, rocks, rescue world, and worm to this shadow target using the current simulation time. Particles and the screen HUD are not included because they are

outside that traversal. The code disables polygon-offset fill afterward and binds framebuffer zero to return to the default window framebuffer. It does not delete or copy the shadow texture; the next pass samples the existing texture written by this pass.

Main Rendering Pass

Framebuffer Clear and Atmospheric Sky

Original source: lines 1737-1758. The main-pass banner begins by setting `g_isShadowPass = false` and restoring the viewport to the actual framebuffer dimensions. `glClearColor(fogColor.r, fogColor.g, fogColor.b, 1)` chooses the warm fog color with alpha one, and `glClear` clears both color and depth. This resets the main render surface independently of the shadow map's depth buffer.

For the sky, face culling is disabled and depth writes are disabled with `glDepthMask(GL_FALSE)`. Depth testing itself remains enabled from startup. The sky program receives `lightDir = sunDir`, `sunColor`, and `invViewProj = inverse(proj * view)`. The inverse transforms projected sample directions into the view/world representation used by the sky shader; no sky cube, external panorama texture, or vehicle model is loaded by this stage.

The runtime binds `g_skyVAO` and issues `glDrawArrays(GL_TRIANGLES, 0, 3)`, a three-vertex screen-filling triangle. The shader generates the desert atmosphere described in the shader chapter. Afterward, depth writes are reenabled and face culling is enabled again. Those are explicit known-state settings, not restoration of queried prior values. The sky is only drawn here, not into the shadow map. If global wireframe mode is active, this range does not force filled sky polygons; filled-mode forcing is reserved for the HUD later.

Scene Matrices, Lighting/Fog Uniforms, and Shadow Texture

Original source: lines 1759-1780. The scene program becomes current. All frame-wide uniforms are assigned before the shared object traversal supplies each model/material.

Uniform	Upload value	Type and count
<code>view</code>	Camera view matrix	One mat4, no transpose.
<code>projection</code>	Perspective proj matrix	One mat4, no transpose.
<code>lightSpaceMatrix</code>	Current shadow projection/view product	One mat4, no transpose.
<code>lightDir</code>	Normalized $(-0.35, 0.12, -1)$	One vec3.
<code>sunColor</code>	$(1.15, 1.04, 0.85)$	One vec3.
<code>ambientColor</code>	$(0.34, 0.38, 0.44)$	One vec3.
<code>viewPos</code>	Final <code>camPosSmoothed</code>	One vec3.
<code>fogColor</code>	$(0.90, 0.74, 0.47)$	One vec3.
<code>fogDensity</code>	0.0022	One float.
<code>wormCenter</code>	Position saved during the shadow pass	One vec3.
<code>collapse</code>	The same attack-time smoothstep scalar	One float.
<code>shadowMap</code>	Texture unit index 0	One integer sampler selection.

Each location is looked up from `g_progScene` at the call site using `glGetUniformLocation`; these frame-wide locations are not cached by this block. Matrix and vector pointers come from `glm::value_ptr`. The usual OpenGL behavior for location -1 is an ignored uniform write; this code does not separately assert the presence of each named uniform. The material helper adds model transform and surface-specific uniforms for every mesh.

Before `drawFullScene`, the runtime activates `GL_TEXTURE0`, binds `g_shadowTex` as `GL_TEXTURE_2D`, and assigns sampler `shadowMap` to integer zero. The sampler receives a texture-unit number, not the texture object's numeric ID.

The shared scene draw then reuses the same visible-object conditions and transforms as the depth pass, now shaded with light, ambient color, shadows, material properties, and fog. The block does not update mission state between passes, so drawing twice does not move the harvester or advance rescue progress twice.

Particle Blend State and Billboard Camera Basis

Original source: lines 1781-1796. The particle stage enables blending, chooses `GL_SRC_ALPHA` and `GL_ONE_MINUS_SRC_ALPHA`, disables depth writes, and disables culling. Depth testing remains on, so dust can be hidden behind already drawn solid geometry while avoiding opaque depth marks that would incorrectly block later transparent particles.

The particle program receives view and projection. Camera-right is extracted as `(view[0][0], view[1][0], view[2][0])`, and camera-up as `(view[0][1], view[1][1], view[2][1])`. GLM indexes a matrix by column and then row, so these expressions gather the desired view-basis rows instead of merely taking one entire stored column. They are uploaded to uniforms `camRight` and `camUp` to orient quad billboards toward the camera.

This stage uses one mesh and per-instance data rather than invoking `drawPart` for each grain of dust. It does not sample the shadow texture through a scene-material draw, create new CPU particle motion, or emit additional particles here. Particle updates already occurred once in the earlier unpaused simulation block.

Particle Fades, Sorting, Buffer Upload, and Instanced Draw

Original source: lines 1797-1814. The CPU instance vector is cleared every frame without discarding its reserved capacity. For every `p` in `g_particles`, it computes `fade = clamp(p.life / 0.5, 0, 1) * clamp((p.maxLife - p.life) / 0.3, 0, 1)`. Since `life` is remaining life, the first factor fades out during the last half-second. The second uses elapsed age, fading in during the first 0.3 seconds. The product limits both ends of the lifespan smoothly through linear clamped factors.

Each push stores `posSize = vec4(p.pos, p.size)` and `colorAlpha = vec4(COL_DUNE_SAND, p.alpha * fade)`. All particles share the dune-sand RGB (0.76, 0.49, 0.23) at this call site; their category-dependent differences are position, size, base alpha, life, and velocity from the particle simulation. The loop pushes every entry, including one whose resulting alpha is zero, rather than culling fully transparent entries here.

The vector is sorted with a comparator that subtracts camera position from each instance position and compares squared distances via `dot(delta, delta)`. A larger distance sorts before a smaller one, giving far-to-near order for alpha compositing. Squared distance avoids a square root without changing distance ordering. It is radial world-space distance, not exact projected eye-depth ordering, and `std::sort` does not promise stable order for equal-distance entries.

The program binds the particle instance VBO and replaces its data store with exactly `instances.size() * sizeof(ParticleInstance)` bytes using `GL_STREAM_DRAW`. This is a new `glBufferData` upload rather than a per-particle `glBufferSubData` series; the driver receives the whole sorted frame's instance array. The quad VAO is then bound and `glDrawElementsInstanced` uses triangle topology, the quad's index count, unsigned-int indices at offset null, and the vector size converted to `GLsizei` as instance count. Attribute divisors configured at startup provide one position/size and color/alpha record per quad instance.

After drawing, the runtime restores depth writes, disables blending, and enables culling. Those changes prepare the known scene state for HUD handling and the next frame. No glow accumulation buffer or post-processing smoke compositor is present. Here smoke-like plumes are ordinary sand-colored blended billboards; the term smoke test later refers to automated render execution and is not this dust particle system.

HUD State Assembly

Crew Counts, Markers, and Basic Metadata

Original source: lines 1815-1827. A new `RescueHudState` `hud` is constructed every frame, using its header-defined default member values. Width and height become current framebuffer dimensions. Rescued, aboard, lost, best, and wave are copied from the mission, and muted is copied from `g_audio.muted`. The latter displays the mute toggle state, not whether an audio device initialized successfully.

`hud.inside` is explicitly reset to zero because its default in the HUD structure is 36. The crew loop increments it for each `Inside` member. For `Running` or `Waiting`, it increments `hud.waiting` and appends (`c.pos.x`, `c.pos.z`) to `crewMarkers`. The new HUD object's waiting counter already starts at zero and marker vector starts empty, so no explicit clearing statement is needed. Other crew states are not placed on this marker list.

These markers use each crew member's stored gameplay position, not the temporary lifted Y position in `drawRescueWorld`; they are two-dimensional map points, so their Y would not be used anyway. The HUD struct's total-crew value remains its default 36 because the main loop does not assign it in this range. The loop counts actual states each frame instead of deriving all numbers by subtracting rescued/lost/aboard from that total.

Timers, Flight Values, Phase Flags, and Map Coordinates

Original source: lines 1828-1846. Every following assignment connects an explicit gameplay or runtime value to the display state.

HUD field	Supplied value	Exact interpretation
<code>missionDuration</code>	<code>g_mission.breachAt</code>	Current wave's planned pre-breach duration.
<code>pursuit</code>	<code>clamp(elapsed / breachAt, 0, 1)</code>	Normalized chase progress, saturated after breach.
<code>wormDistance</code>	<code>wormGap()</code>	The pursuit gap, not camera distance.
<code>extractionRemaining</code>	<code>max(0, 60 - wormAttackTime())</code>	Time relative to attack second sixty; before breach it can exceed sixty.
<code>releasedGroups</code>	Count of all groups with <code>released true</code>	Historical release count, regardless of whether their marker remains visible.
<code>remaining</code>	<code>max(0, breachAt - elapsed)</code>	Nonnegative pre-breach countdown.
<code>altitude</code>	<code>aircraftY - getDuneHeight(aircraftX, aircraftZ)</code>	Actual aircraft terrain clearance, not merely the mission's target-altitude field.
<code>speed</code>	<code>g_ornSpeed</code>	Current flight speed.
<code>boost</code>	<code>g_mission.boost</code>	Current boost reserve.
<code>pickupProgress</code>	<code>g_mission.pickup</code>	Winch progress.
<code>unloadProgress</code>	<code>g_mission.unload</code>	Base unloading progress.
<code>fps</code>	Smoothed local fps	Runtime's damped frame-rate estimate.
<code>prompt</code>	<code>g_mission.prompt</code>	Mission-generated contextual text.
<code>heading</code>	<code>g_ornYaw</code>	Aircraft yaw in the game's degree convention.
<code>title</code>	<code>phase == Title</code>	Enables the HUD's title presentation.
<code>ended</code>	<code>phase == Debrief</code>	Enables results presentation.

HUD field	Supplied value	Exact interpretation
paused	<code>g_mission.paused</code>	Current pause display flag.
player	<code>(g_ornPos.x, g_ornPos.z)</code>	Aircraft map coordinates.
base	<code>(g_mission.base.x, g_mission.base.z)</code>	Base map coordinates.
harvester	<code>(g_harvX, g_harvZ)</code>	Current crawler map coordinates, even if hidden after swallowing.
worm	<code>(wormCenter.x, wormCenter.z)</code>	Position cached earlier in this frame.
pickup	X/Z of a fresh <code>nearestCrewPosition()</code> result	Nearest eligible crew or the helper's harvester fallback.
attackTime	<code>wormAttackTime()</code>	Signed elapsed time relative to breach.

`releasedGroups` is explicitly initialized to zero before counting. The loop does not test whether a released group still has waiting survivors; that filtering is specific to world marker visibility. Before breach, attack time is negative, so `60 - attackTime` exceeds sixty. This caller applies only a lower clamp to extraction remaining, not an upper clamp to sixty. The HUD renderer may format or selectively display values, but the passed field is exactly this expression.

There is no division-by-zero check around `eLapsed / breachAt` in the caller. Normal mission reset supplies a positive duration. Altitude also receives no lower clamp here, so if aircraft Y were below the mathematical terrain height, the raw clearance would be negative. The display renderer's formatting rules are separate from these assignments.

Filled HUD and Restored Wireframe Selection

Original source: lines 1847-1850. Immediately before `drawRescueHud(hud)`, the main loop sets both front and back polygon modes to `GL_FILL`. This ensures text, panels, and HUD geometry stay solid even when F selected wireframe for world geometry. It then restores front/back mode to `GL_LINE` or `GL_FILL` according to `g_wireframe`.

The HUD renderer internally manages its required OpenGL state as described in its own chapter. These three caller statements add a specific rasterization guarantee around that draw. They do not switch the scene back to normal mode permanently or alter `g_wireframe` itself. The HUD is last in the normal rendering order, after sky, solids, and dust, so the later screenshot call includes its final visible result.

Render Smoke Tests and Frame Presentation

Error Sampling, Last-Frame Screenshot, and Swap

Original source: lines 1851-1866. The section banner mentions buffer swap and event polling, but the actual polling operation already occurred near the beginning of the frame. This tail block performs test checks and swaps; it does not contain another `glfwPollEvents()`.

Only render-test modes call `glGetError()` here. If the returned enum is not `GL_NO_ERROR`, standard error receives OpenGL error in frame `<frameCount>: <error>`, `renderFailed` becomes true, and the window is marked for closing. A single `glGetError` call retrieves one error value; this block does not drain a queue of multiple errors or turn each OpenGL operation into a checked call. It also does not compare screenshot pixels, validate object visibility, or impose a frame-time limit. An error can cause an early exit rather than completing all 120 planned frames.

If `frameCount == 119` and `argc > 2`, it calls `captureScreenshot(argv[2])`. Thanks to left-to-right short-circuit evaluation, screenshot capture is not attempted before the final planned frame, without a second argument, or in normal interactive mode. Since the counter begins at zero, frame index 119 is the 120th rendered test frame. A failed capture prints `Screenshot write failed` and sets `renderFailed`; it does not add a separate immediate close call, because the frame limit closes the test afterward anyway. The screenshot is taken before swapping, after the HUD draw, while the default framebuffer is still the current render target.

`glfwSwapBuffers(g_window)` presents the completed frame in both normal and test modes. In render-test mode, `++frameCount` is then evaluated and a count at least 120 sets `should-close` true. In non-test mode, short-circuit evaluation of `renderTest && ...` means `frameCount` is not incremented by this statement at all. A heading or GL error that already requested closure still allows this swap and test increment for the current body. If the user closes a smoke-test window early, the loop exits with fewer frames; no separate assertion here changes an otherwise false `renderFailed` solely because the count is less than 120.

With an uninterrupted test, the fixed 1/60 update interval gives approximately two simulated seconds over 120 rendered frames, in addition to breach/pursuit pre-advance where applicable. The actual wall-clock duration depends on rendering, swap synchronization, driver behavior, and any event waits. No timer-based retry or unattended restart is present.

What the Smoke Test Result Does and Does Not Mean

Original source context: lines 1449-1454, 1564-1570, 1607-1617, 1670-1677, and 1854-1865. The smoke modes exercise real graphics initialization and rendering rather than merely unit-testing state functions. All run the ordinary geometry, both render passes, particles, HUD assembly, and audio calls. Mouse mode additionally checks horizontal view alignment against the aircraft. Breach/pursuit modes select their requested mission times and viewpoints so those scenes are rendered during the bounded run.

A reported pass means `renderFailed` remained false under the checks this program actually performs. It is not proof that every pixel is correct, all requested assets played, no earlier unchecked startup assumption failed, or a user-closed test reached exactly 120 frames. Screenshot success means the file stream accepted the bitmap writes, not that the bitmap contents were compared with a reference image. These distinctions preserve the existing implementation's actual test semantics without claiming hypothetical visual-regression coverage.

Resource Teardown and Exit

Programs, Targets, Renderer Resources, and Mesh Buffers

Original source: lines 1868-1885. After the loop ends normally, cleanup occurs while the window's context still exists. The four main shader programs are deleted in scene, shadow, particle, and sky order. The shadow framebuffer and depth texture are deleted. The particle instance VBO, sky VBO, and sky VAO are deleted next.

`cleanupSandwormMeshes()` releases the worm renderer's resources, and `cleanupRescueHud()` releases HUD resources. Those helpers own resources distinct from the eight basic globals in the following loop. No draw is attempted after these cleanup calls.

The range-based loop then iterates pointers to `g_meshCube`, `g_meshCylinder`, `g_meshSphere`, `g_meshWing`, `g_meshTerrain`, `g_meshQuad`, `g_meshRing`, and `g_meshRock`. For each, it deletes the VAO, VBO, and EBO using that object's stored IDs. A VAO describes attribute/index bindings, while the VBO and EBO hold vertex and index data; deleting only the VAO would not release those buffer objects, so all three deletions are explicit. The order is VAO first, vertex buffer second, element buffer third.

The cleanup does not manually clear the CPU particle vectors, tank vector, or mission crew containers. Their ordinary C++ lifetime ends with program termination. It also does not reset every deleted global ID to zero in this loop because no new render cycle follows. Startup failures that returned before reaching the loop do not run this bottom-of-main sequence, as documented with those branches.

Audio Shutdown, Window Destruction, Timing Output, and Return

Original source: lines 1886-1892. `g_audio.shutdown()` runs after the graphics-resource deletions. The window is then explicitly destroyed. In render-test mode, standard output prints `Render smoke test:` followed by `FAILED` if `renderFailed` is true or `PASS` otherwise, then the frame count and `(glfwGetTime() - smokeStarted)` seconds.

The time is queried after window destruction but before `glfwTerminate`, while GLFW timing remains available. Because `smokeStarted` was taken after setup and fast-forward, this duration measures the render-loop interval plus its normal resource cleanup, audio shutdown, and window destruction, not full process startup. The frame count is the

number incremented at the end of rendered test frames; iconified waits do not increment it.

Finally `glfwTerminate()` shuts down GLFW, and `main` returns 1 for a recorded render failure or 0 otherwise. Normal interactive execution ordinarily leaves `renderFailed` false because the failure-setting render checks are guarded by test modes, so its normal exit returns zero. The earlier `--test-game` return, GLFW/window/GLAD -1 failures, and shader/HUD startup failure 1 remain separate exit paths. The final brace at original line 1892 ends `main` and the inspected source file.

Coverage Ledger

Original Lines Accounted For

This ledger is an index to the detailed explanations above. Blank separator lines have no executable behavior. Every nonblank line in the requested original interval is covered, including descriptive banners, includes, declarations, assignments, branches, loops, calls, lambda bodies, return statements, and closing braces. Line references are deliberately original-source references rather than promises about numbering after relocation.

Original range	Covered source responsibility
968-1001	Ornithopter banner, signature, inputs, six materials, boost emission selection.
1002-1018	Central pod, nose, probe, canopy/frame, paired intakes.
1019-1035	Four gimbals, turbine bodies/nozzles, conditional exhaust length and both exhaust draws.
1036-1048	Three tail sections, paired canted fins, paired landing skids.
1049-1081	Wing banner, waveforms, five-field definition, all eight blade entries.
1082-1101	Wing iteration, ordered matrices, twist, mirrored span, culling, draw, function end.
1103-1119	Harvester banner/signature, six materials, hopper and upper deck.
1120-1139	Track offsets, nested unit loops, housing, wheel/bar loop, ten-pad ellipse and rotations.
1141-1153	Cutter, door material, door, ramp, luminous scoop, two separators.
1154-1168	Bridge, viewport, floodlights, exhaust stacks/rims, harvester function end.
1170-1192	Tank banner/signature, four materials, skids/crosspieces, two-station support loop.
1193-1210	Vessel cylinder, two full spherical heads, bands, hatch, valve, sight indicator, function end.
1212-1225	Rock banner/signature, strata materials/category, four transformed rock meshes, function end.
1227-1245	Worm/HUD includes, rescue signature/materials, base root, pad/ring/cross, four beacons.
1246-1261	Group eligibility, member counting, terrain-normal alignment, amber ring/pole/light.
1262-1278	Crew eligibility, visual pickup lift, stride selection, complete body and locator draws.
1279-1293	Rope eligibility/endpoints/length/orientation, cyan cable draw, worm arguments, function end.

Original range	Covered source responsibility
1295-1316	Master banner/signature, terrain material/draw, aircraft loss branch and attitude matrix.
1317-1333	Harvester visibility boundary, sinking, heading-relative slope rotations, swallowing tilt/draw.
1334-1354	Tank boundary and roots, eight terrain-embedded rock sites, rescue traversal, function end.
1356-1374	Callback banner, positive framebuffer resize, logical cursor recentering/reset.
1375-1387	Cursor eligibility, early reset/return, logical dimensions and hover helper.
1388-1427	Key bounds/press/release, Escape/F/C/Enter/R/M/P/F11, fullscreen branch, function end.
1429-1439	Entry banner, screenshot allocation/readback/open check, little-endian lambda.
1440-1446	Complete BMP header, raw pixels, stream status and screenshot function end.
1448-1459	Main signature, mission-test early return, four render flags, GLFW failure.
1460-1485	GL version/profile and monitor hints, multisampling, first window and fallback/error branch.
1486-1505	Current context/framebuffer size, named callbacks, three lambda callbacks, VSync.
1506-1526	GLAD failure path, audio startup, diagnostic output, initial depth/MSAA/cull state.
1527-1543	Eight reusable meshes, worm mesh initialization, four shader-program builds.
1544-1563	Shadow/sky/HUD setup, startup shader failure, particles/VBO/attributes/divisors/reserve/reset.
1564-1578	Breach/pursuit fixed-substep pre-advance, aircraft placement, sun/ambient/fog constants.
1579-1593	Initial timing, smoothed camera/animation/FPS state, revision/failure/count/timer, loop banner.
1594-1606	Loop condition, iconified wait/continue, wall-time delta/cap/copy, event polling.
1607-1618	Render-test fixed dt/unpause, synthetic mouse/W/camera modes, FPS filtering.
1619-1630	Bounded mission updates, debrief clock, animation time, title wings, particles, clock handoff.
1631-1643	Camera banner, revision reset, pause-gated Up/Down elevation bounds.
1644-1654	Aircraft target/helper offset, breach and pursuit override branches.
1655-1669	Desired terrain safety, height/target smoothing, heading-locked X/Z, test X/Z, final clearance.
1670-1682	Mouse heading invariant/error/close, view, framebuffer aspect, perspective projection.

Original range	Covered source responsibility
1683-1704	Nearest crew/distance calculation, all eighteen spatial-audio arguments.
1705-1721	Shadow banner/flag/viewport/FBO/depth clear, player-ground center, ortho and light matrices.
1722-1736	Shadow program/uniforms, worm/collapse, polygon bias, complete scene, target unbind.
1737-1758	Main banner/flag/viewport/clear, sky states/uniforms/inverse matrix/triangle/state restoration.
1759-1780	Scene program and all frame uniforms, unit-zero shadow texture, complete scene traversal.
1781-1796	Particle blend/depth/cull state, matrices, camera-right/up uniforms.
1797-1814	Instance clearing/fade/packing/sorting, stream upload/instanced quad draw, state reset.
1815-1827	Fresh HUD, size/counters/mute, inside and outside crew counting/map markers.
1828-1846	HUD timers/progress/gap/groups/flight data/text/flags/map coordinates/attack time.
1847-1850	Filled HUD draw and user wireframe mode restoration.
1851-1866	Presentation banner, render GL error, optional last-frame BMP, swap/count/close, loop end.
1868-1885	Four programs, shadow objects, particle/sky resources, worm/HUD cleanup, eight mesh deletions.
1886-1892	Audio shutdown, window destruction, test result/time output, GLFW termination, return/file end.

The requested interval ends at the end of the original file; there is no further scene or runtime code after original line 1892. This chapter explains that interval without modifying source behavior, adding features, or duplicating the final full-source appendix.

Chapter 4: Mission Rules, Flight Controls, and Tests

This chapter explains the complete gameplay header and the complete mission-test header in beginner-friendly terms. The original files were `arrakis_game.h` and `arrakis_tests.h` at the project root when this chapter was researched. In the reorganized project their locations are `src/arrakis_game.h` and `tests/arrakis_tests.h`. Every source range in a heading below refers to the original header, not to this Markdown file. The numbered source appendices provide the exact text; the explanations here describe what that text does rather than replacing explanations with a copied listing.

The gameplay header has 307 original lines. The test header has 1,041 original lines. The ranges below collectively account for every nonblank line in both. Opening and closing braces belong to the constructs explained in their ranges; empty separator lines have no runtime behavior. Both headers depend on types, variables, libraries, and functions already introduced by the translation unit that includes them. They are not independently compilable programs.

Reading the Mission

The player controls an ornithopter, a fictional aircraft with flapping wings. A moving harvester carries 36 people. Those people leave in timed groups, run to fixed gathering points, and wait for pickup. Holding Space near people, while low and slow enough, winches them into an eight-person cabin. Holding Space near the base unloads the whole cabin after a separate dwell interval. Only delivered people contribute to the rescue score.

A pursuing worm approaches the moving harvester. Its danger rules depend on elapsed mission time, the time of breach, horizontal distance, and, for the aircraft, height. Crew aboard the aircraft are protected from ordinary local crew hazards but not from an aircraft collision or the final timeout. Crew already delivered remain safe even if the aircraft is subsequently lost.

Here, a `glm::vec3` is a three-component vector with *x*, *y*, and *z*. The world uses *y* for height and the *x*, *z* plane for ground positions. A `glm::vec2` holds two components. For the mouse these are horizontal and vertical normalized input; for distance checks they usually stand for world *x*, *z*. Distances are expressed in world units, treated as meters by the test messages. Times are seconds, yaw and camera pitch are stored in degrees, and trigonometric functions receive radians.

The notation *dt* means the amount of simulated time represented by one update. A frame at 120 updates per second has a *dt* near 1/120. Multiplying a speed by *dt* gives the movement for that update. This is essential to avoid rules that change simply because the program draws more frames, although not every integration in this file is exactly frame-rate independent.

Several small mathematical operations recur throughout the chapter. `clamp(value, minimum, maximum)` returns the minimum when *value* is below it, the maximum when above it, and *value* otherwise. `min` chooses the lesser of two inputs and `max` the greater. `abs` measures magnitude without sign. A vector's length is its Euclidean magnitude; normalizing a nonzero vector divides it by that length to preserve direction while making its length one. The code checks for zero before normalizing movement input.

`mix(a, b, w)` means $a * (1 - w) + b * w$. With weight zero it returns *a*; with weight one it returns *b*. The same operation works on each component of a vector. Here most smoothing weights are $1 - \exp(-k * dt)$, where `exp` is the exponential function and *k* is a positive response rate. Over a constant-target interval *t*, the fraction of the original error remaining is $\exp(-k * t)$. The characteristic time is 1/*k*: approximately 0.125 seconds for rate eight, 0.167 for six, 0.182 for 5.5, 0.083 for 12, and 0.25 for four. A smaller characteristic time means faster response, not a fixed delay after which the value suddenly snaps to its target.

A dot product multiplies corresponding vector components and sums them. For unit directions it equals the cosine of the angle between them, so a value near one means nearly identical directions and a value near minus one means opposite directions. A cross product returns a perpendicular vector with an order-dependent sign. Taking forward cross world-up gives aircraft-right in this project's coordinate convention. Converting degrees to radians multiplies by $\pi/180$; converting radians to degrees multiplies by $180/\pi$.

In C++, `if` chooses whether a statement or block runs, `else` selects an alternative, `continue` skips the remainder of the current loop iteration, and `return` leaves a function. Conditions joined by `&&` require both operands, while `||` requires either; they short-circuit, so the second operand need not be evaluated once the result is already known. Prefix `++` and `--` change a counter by one. The references used by range-based loops operate on the original objects, while constant references allow reading without changing them. These details explain why the update can mutate every person's state in place and why comparison loops can stop safely when a mismatch is found.

Game Types and Storage

Game Lines 1-4: Inclusion and State Enumerations

Line 1 uses `#pragma once` to avoid processing this header more than once within a translation unit. This does not make its globals or ordinary function definitions safe to duplicate across many independently compiled translation units. The project includes them as part of its existing compilation structure.

`MissionPhase` is a scoped enumeration with `Title`, `Flying`, and `Debrief`. With no explicit assigned values, their underlying values begin at zero in declaration order, but the code uses their names rather than relying on numeric values. `Title` is the pre-mission state, `Flying` enables simulation, and `Debrief` is the finished state. A pause is not a fourth phase: it is a separate Boolean within a mission.

`CrewState` has six scoped values, likewise in declaration order: `Inside`, `Running`, `Waiting`, `Aboard`, `Safe`, and `Lost`. `Inside` means still attached to the harvester's evacuation exit. `Running` means moving to a scheduled destination. `Waiting` means standing at that destination. `Aboard` means counted in the aircraft cabin. `Safe` means unloaded and scored. `Lost` means no longer rescuable. These are mutually exclusive because each person stores one enumeration value, not several independent flags.

The usual successful path is `Inside -> Running -> Waiting -> Aboard -> Safe`, but pickup also accepts `Running`, so waiting is not compulsory. Local hazards can turn `Running` or `Waiting` into `Lost`; swallowing can turn `Inside` into `Lost`; aircraft loss or timeout converts every state other than `Safe` and already `Lost` into `Lost`. A mission reset creates an entirely new population rather than reversing those transitions on existing people.

Game Lines 5-11: Every Evacuee Field

`Evacuee` represents one crew member. `pos{0}` initializes all three position components to zero, and `destination{0}` does the same for the target position. These are world-space values, not coordinates relative to a moving harvester. `state` initially equals `CrewState::Inside`.

`release` is a floating-point scheduled release time, initially zero. `group` is an integer index identifying the person's evacuation group, initially zero. `slot` is an integer identifying their position within that group, also initially zero. The declaration places `group` and `slot` on one line but initializes each separately. A freshly constructed person therefore has a valid default state, but mission setup must assign their real route position, release schedule, group, and slot before gameplay.

The person has no individual health, score, velocity, animation timer, or inventory. Walking speed is supplied by the update function. The group index selects which release loop will activate the person, while the slot determines the spacing within the gathering cluster. The duplicate release value on the person is used to calculate how much walking time is available when a frame crosses the release threshold.

Game Lines 12-17: Every Evacuation Group Field

`EvacuationGroup` stores `count`, initially zero, for the number of people assigned to the group. `release`, initially zero, records the group's scheduled release time. `center{0}` is a three-component world-space cluster center, initially the origin. `released`, initially `false`, prevents the release operation from being repeated in later updates.

Before release, `reset` stores the initial harvester position in `center`; this is temporary. At release, the code replaces it with the actual scheduled gathering point. The group has no list of member pointers. Instead, the update scans the mission's crew vector and selects people whose group index matches the group being released.

Game Lines 18-32: Every Mission Field and Default

RescueMission contains the state of one attempt. `phase` initially equals `Title`. `paused`, `planeLost`, and `boostLocked` are initially `false`. `paused` stops the update before any simulation work. `planeLost` records a worm collision with the aircraft. `boostLocked` prevents held Shift from immediately reactivating boost after energy runs low.

The integer fields are `wave = 1`, `rescued = 0`, `aboard = 0`, `lost = 0`, and `best = 0`. `wave` affects the breach timer, not crew count or cabin capacity. `rescued` counts delivered people. `aboard` counts current cabin occupants. `lost` counts people marked lost. `best` is the highest delivered total retained across resets in the current process. This header does not save that record to disk or calculate a separate cumulative score across waves.

The floating-point fields are `elapsed = 0`, `breachAt = 210`, `altitude = 8`, and `boost = 1`. `elapsed` is the attempt's simulation clock. `breachAt` is an absolute elapsed-time threshold. `altitude` is desired terrain-relative height, not necessarily the aircraft's instantaneous measured height. `boost` is a normalized resource from zero to one.

`harvesterYaw = 0` and `harvesterTravel = 0` describe orientation and accumulated horizontal travel. `wormYaw = 90` is a stored fixed orientation; no function in this header changes it. `pickup = 0` and `unload = 0` are normalized dwell progress. Their completion threshold is one. `target = -1` means no current pickup person; nonnegative values are indices into crew.

`prompt` starts as an empty `std::string` and is replaced during active updates with instruction text. `base{55, 0, 55}` gives the base's horizontal location; reset later fills in its terrain height. `crew` and `groups` are initially empty standard-library vectors. Their sizes and contents are populated by reset.

These defaults are significant because `reset` replaces the entire mission object with `RescueMission{}`. Any field that is not explicitly restored afterward returns to exactly these values. For example, pause, plane loss, boost lock, prompts, targets, travel, and old populations disappear, while `best` and `wave` are specially preserved or advanced.

Game Lines 33-39: Every Global and Rock Site

`g_mission` is the global mission object and begins with the defaults above. `g_missionRevision` starts at zero and increments whenever `resetMission` is called. It can let other systems recognize a new attempt; this file does not otherwise read it. `g_mouseHover(0)` begins with both mouse-input axes zero. `g_mouseTurnRate = 0` begins with no stored angular inertia.

`RESCUE_CAPACITY` is a compile-time integer constant of eight. It is the cabin limit used during boarding and by several tests. It is not an adjustable per-wave mission field.

`g_rockSites` is a fixed array of eight horizontal obstacle centers: (45, -65), (-55, 40), (90, 30), (-90, -70), (15, 95), (-25, -115), (120, -25), and (-130, 85). The pairs represent x, z, not x, y. The flight update uses these centers to increase terrain clearance nearby. It does not calculate collisions from rendered rock triangles or assign each rock a separate height.

Globals such as `g_ornPos`, `g_ornVel`, `g_ornYaw`, `g_keys`, `g_harvX`, `g_harvZ`, `g_audio`, and `g_tanks` are used but not declared here. Their definitions and, where relevant, their callbacks and rendering uses belong to other chapters. The distinction matters: this header supplies the rules, not the entire window/input/audio implementation.

World and Input Helpers

Game Lines 41-46: Horizontal Distance and Current Harvester Position

`horizontalDistance(a, b)` subtracts the two points' x and z components, forms a two-component vector, and returns its length. Mathematically this is $\sqrt{(a.x - b.x)^2 + (a.z - b.z)^2}$. Height differences are deliberately ignored. Pickup, base arrival, and worm proximity therefore have separate horizontal and vertical requirements rather than a single spherical distance check.

`harvesterPosition()` constructs a position from the external `g_harvX` and `g_harvZ`. Its height is freshly queried from `getDuneHeight` at those coordinates. The height is not separately stored in a harvester global. If the terrain function changes, this helper reflects that change on its next call.

Game Lines 47-60: Analytic Route, Tangent Yaw, and Forward Direction

`harvesterRoute(time)` calculates an absolute route position directly from a time value. The horizontal formulas are $x = -40 + 0.62 \cdot \text{time} + 15 \cdot \sin(0.045 \cdot \text{time})$ and $z = -55 + 22 \cdot \sin(0.032 \cdot \text{time}) + 9 \cdot \sin(0.071 \cdot \text{time})$. At zero time the harvester is at (-40, -55) horizontally. The linear term generally carries it east, while three sine terms create the wandering path. Height is the terrain height at the calculated position.

These are analytic coordinates: the function does not move a previous position incrementally and does not modify mission state. Asking for time six always gives the same result, regardless of the frame that noticed a release. The helper itself does not clamp time; clamping happens in `updateHarvester`. Scheduled release code deliberately calls this raw route at the release's own time.

`harvesterRouteYaw(time)` derives the horizontal tangent. Differentiating the x formula gives $dx = 0.62 + 0.675 \cdot \cos(0.045 \cdot \text{time})$ because $15 \cdot 0.045 = 0.675$. Differentiating the z formula gives $dz = 0.704 \cdot \cos(0.032 \cdot \text{time}) + 0.639 \cdot \cos(0.071 \cdot \text{time})$ because $22 \cdot 0.032 = 0.704$ and $9 \cdot 0.071 = 0.639$.

The returned yaw is the degree conversion of $\text{atan2}(-dx, -dz)$. This sign and argument order align a model whose local forward direction is negative Z with the tangent. `atan2` accounts for quadrants rather than dividing one derivative by the other. This is a horizontal heading; it does not tilt the harvester to match the vertical terrain slope.

`harvesterForward(yaw)` converts degrees to radians and returns $(-\sin(\text{angle}), 0, -\cos(\text{angle}))$. It is a horizontal unit direction. At zero yaw it points toward negative Z. This same convention appears in aircraft flight, although `wormYaw` is a separate stored model-orientation value and should not be interpreted as an aircraft heading calculation.

Game Lines 61-78: Harvester Updates and Worm Geometry

`updateHarvester(elapsed)` first clamps the supplied elapsed time into $[0, \text{breachAt}]$. Negative times select the beginning; times after breach select the breach pose. It reads the previous current position, evaluates the next route position, and adds the horizontal distance between them to `harvesterTravel`. It then writes the new external x/z globals and the route tangent yaw.

Accumulated travel is a sum of straight chords between sampled positions, not an exact integral of curved-route arc length. Its value can differ slightly with update frequency. Calling the helper with nonmonotonic times can also add backward travel; this helper does not reject such calls. Once repeated calls clamp to the same breach pose, the added distance is zero and the pose and accumulated travel stop changing.

`wormGap()` calculates $\text{progress} = \text{clamp}(\text{elapsed}/\text{breachAt}, 0, 1)$ and linearly interpolates from 220 to 18. Equivalently, the gap is $220 - 202 \cdot \text{progress}$. During a normal first wave it closes by $202/210$, approximately 0.962 world units per second. Later waves reach the same endpoint sooner. After breach the gap remains 18. The implementation assumes a positive nonzero breach time, which normal reset guarantees.

`wormPosition()` begins with the current harvester position, subtracts the gap from x, leaves z unchanged, and recomputes terrain height at the worm's new x/z. Thus the worm is always west of the harvester, not necessarily behind the harvester's current tangent direction. It does not independently steer toward a person or aircraft. Its motion follows this geometric relationship.

`wormAttackTime()` returns $\text{elapsed} - \text{breachAt}$. A negative answer means before breach, zero means the exact breach instant, and a positive answer measures seconds since breach. Most hazard windows below are expressed in this relative time, so shortening a wave automatically shifts them earlier in absolute mission time.

Game Lines 80-89: Nearest Crew Position

`nearestCrewPosition()` initializes a search radius of 10,000 and a fallback point equal to the current harvester position. It loops over every person by constant reference, skipping states other than `Waiting` and `Running`. For each eligible person it measures horizontal distance from the aircraft, and a strictly smaller distance replaces the current best position.

The helper returns a position, not a crew index, and has no 12-unit pickup radius. If no eligible person is closer than the initial 10,000-unit bound, it returns the harvester fallback. Equal-distance ties retain the first previously selected person because the comparison is strict. It does not change the pickup target or board anyone.

Game Lines 91-100: Cursor Validation, Normalization, and Deadzone

`setMouseHover(x, y, width, height)` first clears both hover axes. It returns immediately if width or height is nonpositive, either coordinate is nonfinite, or either coordinate lies outside the window. Coordinates exactly zero or exactly width/height are accepted because the boundary comparisons use `<` and `>`, not `<=` and `>=`.

For valid input, horizontal position becomes $2 \cdot x / \text{width} - 1$ and vertical position becomes $2 \cdot y / \text{height} - 1$. A left or top edge is -1, the center is zero, and a right or bottom edge is +1. The intermediate expressions use the double cursor coordinates before conversion to float for the deadzone function.

The local lambda maps one normalized value to `copysign(max(0, (abs(value) - 0.12) / 0.88), value)`. The central magnitude of 0.12 produces zero, and the rest is rescaled so magnitude one remains one. The deadzone occupies six percent of window width or height on either side of center, because the normalization doubles pixel displacement. In a 1,000-pixel-wide window, horizontal coordinates 440 through 560 are in that neutral region.

`copysign` keeps the original sign, including a possible negative zero; comparisons and vector lengths still treat that zero as neutral. Each axis is treated separately. There is no radial deadzone. A corner can therefore produce $(1, 1)$, whose two-component length is greater than one. Invalid input clears both axes even if only one coordinate was wrong. This function only stores arithmetic input: it does not itself steer, move, advance time, or update turn inertia.

Game Lines 102-118: Flight Direction and Camera Helpers

`flightForward()` uses the aircraft's current `g_ornYaw` and the same $(-\sin(\text{yaw}), 0, -\cos(\text{yaw}))$ convention as the harvester helper. It does not inspect velocity. Reversing or strafing therefore does not automatically aim the nose in the movement direction.

`flightCameraPitch()` returns `clamp(12 - g_mouseHover.y*22 + g_camOrbitPitch, 6, 65)`. With a centered mouse and zero orbit adjustment, pitch is 12 degrees. Top-edge hover has $y = -1$ and gives 34 degrees. Bottom-edge hover has $y = +1$ and would give -10 before clamping, so its result is six degrees. The separately supplied orbit adjustment can raise the result to the overall 65-degree maximum or lower it to six. This helper calculates a value; it does not implement the callback that changes orbit adjustment.

`flightCameraOffset(mode)` starts with `behind = -flightForward()`. Mode 2 returns 26 units behind and 100 units upward, independent of mouse pitch. Otherwise, mode 1 uses distance 20 and every other integer uses distance 40. Thus unknown modes fall through to the ordinary follow calculation rather than producing an error.

For those non-overview modes, horizontal distance behind is $\text{distance} \cdot \cos(\text{pitch})$ and height is $\text{distance} \cdot \sin(\text{pitch})$. Mode 1 adds another 2.2 vertical units. The ordinary follow offset has length 40, and the close offset has length 20 after subtracting the extra height. All offsets remain horizontally behind the nose, which keeps camera screen-right consistent with aircraft-right. The helper returns an offset, not an absolute eye position or a view matrix; the runtime uses it to place the camera.

Starting and Finishing Attempts

Game Lines 120-140: Reset Ordering and Flight Restoration

`resetMission(start, next=false)` is the attempt initializer. `start` chooses active play versus title, while `next` determines whether to increment the current wave. The default second argument means a one-argument call retries the same wave.

It first increments the mission revision and calls `g_audio.resetMission()`. Audio internals are explained separately. It saves the previous best and either preserves wave or calculates $\text{wave} + 1$. Then it replaces the mission with a default-constructed object and restores those two saved values.

The new breach threshold is $\max(150, 210 - (\text{wave} - 1) * 10)$. Wave one gets 210 seconds, wave two 200, wave three 190, wave four 180, wave five 170, wave six 160, and wave seven and later 150. Nothing here prevents callers from changing wave to an unusual number outside normal play; the documented progression describes ordinary positive waves.

The phase becomes `Flying` when `start` is true and `Title` otherwise. The harvester is restored to `harvesterRoute(0)`, its x/z globals are replaced, and its yaw is recomputed from the route tangent. The base's y is replaced with terrain height. The aircraft is placed eight units above that base and receives zero velocity and yaw.

Both hover axes, stored turn rate, aircraft speed, pitch, roll, and camera orbit pitch are zeroed. The chained assignment to speed, pitch, and roll resets all three values. Importantly, the ordinary reset does not clear `g_keys`, does not explicitly clear `g_isBoosting`, and does not reset `g_wingPhase`. The testing helper `fresh` handles those additional globals. A reset should not be described as clearing every application-global variable.

Game Lines 141-154: Exact Population and Release Schedule

Population construction begins with `remaining = 36`. The while loop continues until none remain. For each iteration, the group index is the current number of groups. Desired size is $1 + \text{group} \% 4$, capped by remaining people. Release time is $6 + \text{group} * 7$ seconds.

The group is appended with its count, scheduled release, initial harvester position, and `released=false`. A nested for loop creates slots from zero through `count - 1`. Each new person's default state remains `Inside`, while release, group index, and slot are assigned explicitly. Both position and destination initially become the starting harvester position. Each person is appended, then the outer loop subtracts that group's count from remaining.

The exact result is 15 groups. Their sizes are 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, totaling 36. The release schedule is 6, 13, 20, 27, 34, 41, 48, 55, 62, 69, 76, 83, 90, 97, 104. The last group's three people complete the population without truncating its nominal size. No random generator determines these numbers. The schedule is unchanged on later waves, so even the 150-second breach floor remains after the final scheduled release.

The loops assign identity by vector position and group/slot fields, not by a separately allocated identifier. Vector insertion order later matters for nearest-person ties. All people in a group share a release time but receive different destinations when their group is activated.

Game Lines 155-159: Tank Reset

The external tank vector is cleared, then three aggregate records are inserted. Their positions and accompanying values are $(-12, 0, -26)$, $(20, 1)$; $(-19, 0, -32)$, $(-15, 1)$; and $(-26, 0, -23)$, $(10, 1)$. The game header supplies the literal records but does not declare the tank structure; the scene chapter identifies how its orientation and scale fields are rendered.

These y coordinates are explicitly zero in the stored records. This routine does not query terrain for them, and this header does not give tanks an independent collision, crew population, or mission counter. Clearing the vector means a normal mission reset replaces any previous tank entries with these three.

Game Lines 161-166: Finishing Without a Separate Win Flag

`finishMission()` changes phase to `Debrief`, sets `best` to the larger of its existing value and the current delivered count, clears both dwell-progress values, and zeros aircraft velocity. It does not itself mark unresolved crew lost, empty the cabin, change the prompt, or decide whether the result is a success. The calling update branches do their own loss reconciliation before invoking it.

There is no won Boolean or `Win` phase. Delivering all 36 without losses is the full-success scenario, but delivering the final survivors after other crew are lost also ends naturally in `Debrief`. Direct callers can invoke `finishMission()` on an unresolved population, as the next-wave test intentionally does; the function alone does not enforce a finished-population invariant.

It also does not reset `g_orbSpeed`, pitch, roll, wing phase, boost status, or turn rate. Because later mission updates return immediately in `Debrief`, those values can remain as the last-frame snapshot even though velocity is now zero.

The tests correctly check frozen simulation rather than assuming all display or animation values become their defaults.

The Active Update

Game Lines 168-174: Guard, Clock, Harvester, and Winch Input

`updateMission(dt)` takes a reference named `m` to the global mission, avoiding repeated long names and ensuring writes affect the real object. If `phase` is anything other than `Flying`, or if `pause` is true, it immediately returns. `Title`, `debrief`, and `pause` therefore freeze all work within this function, including the clock, routes, resources, crew, hazards, and flight animation.

For active play it first adds `dt` to elapsed time, then updates the harvester at the new elapsed time, then calculates attack time. Thresholds in the frame therefore see the end-of-step clock. `winch` is a constant Boolean snapshot of the Space key for this update. No mouse click is required to steer or winch; mouse position and a keyboard Space state are separate inputs.

The function does not validate that `dt` is finite, nonnegative, or reasonably small. Normal application timing and test fixtures provide suitable values. A zero `dt` still evaluates release and hazard conditions and can finish a mission already placed at its timeout. That behavior is deliberately used in tests. Negative or nonfinite `dt` is not covered by these tests and should not be advertised as supported.

Game Lines 175-182: Steering and Exact Angular Smoothing

Steering combines normalized horizontal hover, a +1 contribution from Right, and a -1 contribution from Left, then clamps the result into `[-1, 1]`. Both arrows together cancel. An arrow can reinforce or oppose mouse hover, but the clamp limits total strength. Desired angular rate is `turnRate = -steer * 80`, so full right gives -80 degrees per second and full left gives +80.

The previous actual rate is `g_mouseTurnRate`. With damping constant eight per second, `turnDecay = exp(-8*dt)`. The new stored rate is `mix(turnRate, oldRate, turnDecay)`, or `turnRate + (oldRate - turnRate) * exp(-8*dt)`. It approaches the requested rate exponentially rather than switching instantly.

Yaw uses the exact integral of that exponential over the step: its change is `turnRate*dt + (oldRate - turnRate) * (1 - exp(-8*dt)) / 8`. This is more accurate than first computing the new rate and multiplying that end-of-step rate by `dt`. With a constant steering command it agrees with the continuous solution across different step sizes, apart from floating-point error.

`std::remainder(..., 360)` wraps yaw using the nearest multiple of 360. Its result is around the signed half-turn range rather than the `[0, 360)` interval returned by some wrap conventions. Equivalent headings such as 359 and -1 therefore remain physically identical even if their stored numbers differ.

Roll moves exponentially toward `g_mouseTurnRate * 0.28` with rate six per second. At a settled full turn, the target magnitude is 22.4 degrees. This is a visual bank based on turn rate, not a cause of sideways acceleration. Because the roll target itself evolves during the step, the same exact-yaw guarantee should not automatically be claimed for the entire visual roll trajectory.

Game Lines 183-195: Translation, Boost Lock, and Velocity

The update computes forward from the current yaw and right as `cross(forward, (0, 1, 0))`. At zero yaw these are negative Z and positive X. D contributes +right, A contributes -right, W contributes +forward, and S contributes -forward. Opposite held keys cancel on their respective axes.

If the resulting input vector has positive length, it is normalized. This prevents diagonal W+D movement from being $\sqrt{2}$ times faster than a single direction. A zero vector stays zero, avoiding division by zero. Translation remains relative to nose orientation; neither desired movement nor velocity realigns yaw.

Boost lock is evaluated in order. Releasing left Shift clears the lock first. A resource level at or below 0.04 then sets it again. Actual boosting requires held left Shift, an unlocked resource, no winch, and nonzero movement input. Holding Shift alone while stationary is not boosting; holding Space suppresses boost even when Shift and movement are also

held.

Resource then changes by $dt * (-0.22)$ while boosting or $dt * (0.14)$ otherwise, clamped into $[0, 1]$. Full-resource continuous use reaches the 0.04 lock threshold in approximately $(1 - 0.04) / 0.22 = 4.36$ seconds under small steps. Recharging from zero to one takes approximately $1 / 0.14 = 7.14$ seconds while not boosting. A held Shift cannot automatically unlock after recharge: release is needed, and if that release happens while energy is still at or below 0.04 the next condition relocks immediately. Threshold decisions use the resource before this frame's resource change.

Desired velocity is normalized input times 48 while actually boosting and times 28 otherwise. If Space is held, desired velocity is reduced to ten percent, giving at most 2.8 with ordinary translation. Holding Space therefore permits slow movement rather than forcing a stationary aircraft.

Velocity approaches desired velocity using $1 - \exp(-dt * k)$, with $k=12$ while winching and $k=5.5$ otherwise. With a constant target this smoothing matches exponential damping. The aircraft position then advances by the resulting velocity times dt . That positional integration uses the new sampled velocity, not the analytic integral used for yaw, so complete movement is not exactly independent of step size. Changing heading and changing boost targets introduce additional per-step effects.

Game Lines 196-214: Bounds, Height, Obstacle Clearance, and Animation

The aircraft's x and z are each clamped into $[-160, 160]$. This is an axis-aligned square, not a circular map boundary. Velocity is not zeroed or clipped on hitting an edge, so a craft pressing against the boundary can still have a nonzero speed value. g_or_nSpeed is the length of its velocity after the update, not displacement divided by dt .

Altitude input is $(Q - E) * 15 * dt$, clamped between four and 55. Q raises desired altitude; E lowers it; both cancel. With Space held, the already clamped desired altitude is then exponentially mixed toward six at rate four. The order means altitude keys can still influence the value while winching, but the winch's pull toward six acts afterward.

ground is terrain height under the aircraft's newly updated horizontal position. $clearance$ starts as desired altitude. For each of eight rock sites, the code measures horizontal distance and computes $avoid = 1 - smoothstep(8, 17, distance)$. Specifically, let $u = clamp((distance - 8) / 9, 0, 1)$; $smoothstep$ is $u * u * (3 - 2 * u)$, and $avoid$ is one minus that result. At distance eight or less, $avoid$ is one. At 17 or more, it is zero. Between them it changes smoothly with the $smoothstep$ cubic rather than linearly. $Clearance$ becomes the maximum of its current value and $13 * avoid$. Thus close rocks request at least 13 units, and the outer region fades that extra request.

There is also harvester avoidance. While attack time is less than 11, and the craft is within strictly eight x units and strictly seven z units of the harvester, $clearance$ becomes at least 12. This is a rectangle, not a radius. The condition includes all pre-breach times because negative attack times are less than 11. It stops at attack 11, one second before the Inside-crew swallowing threshold of 12. It is a height-assistance rule, not a harvester impact/failure test.

Aircraft y approaches $ground + clearance$ exponentially at rate eight. A subsequent hard maximum guarantees y is at least $ground + 3$ immediately. The hard floor protects against abrupt terrain changes; the 12/13-unit assistance is only a smoothed target and does not guarantee instantaneous clearance above every rendered obstacle.

Aircraft pitch approaches $-speed * 0.3$ at rate six. Faster horizontal motion therefore tilts the display downward more strongly. Wing phase increases by $36 * dt$ during actual boost or $23 * dt$ otherwise, including stationary active flight. The phase is not wrapped here. Q/E height changes and y smoothing do not add a vertical component to the translational velocity vector; this is terrain-following arcade flight, not full rigid-body aerodynamics.

Game Lines 215-233: Releasing Groups at the Scheduled Pose

The update loops over all groups by integer index. It skips a group if already released or if elapsed time is still below its release time. A group can therefore activate exactly at its schedule, and one coarse update can activate several due groups.

For an activating group it evaluates the route and tangent yaw at $group.release$, not the current elapsed time.

Forward and right are constructed at that scheduled pose. The exit is $origin + right * 6.1 - forward * 1.2$. The

gathering center is another 14 units along right from the exit, and its y is terrain height. `released` becomes true before processing members, preventing future destination recomputation.

The nested crew scan selects only members of this group still in `Inside`. Those people become `Running` and start at the exit. Their destination is center plus a forward spread of $1.7 * (\text{slot} - (\text{count} - 1) * 0.5)$ and an additional right spread of $1.3 * (\text{slot} \% 2)$. Centering the forward offsets around zero distributes slots symmetrically along forward; alternating even/odd slots creates a second small row sideways. Destination y is terrain height at each person's own destination.

For a one-person group, slot zero has neither spread and its destination equals the center. For larger groups, not everyone stands exactly at the center. The exit's initial y comes from the route's origin because horizontal vectors have zero y, but the later crew loop sets actual position height to local terrain before hazards and pickup.

The release loop's work is proportional to groups times crew because each released group scans the whole population. With 15 groups and 36 people this is small. More importantly, setting a group's flag while none of its people remain `Inside` is permitted; the flag records scheduled activation, not a successful evacuation count.

Game Lines 234-250: Walking and Terrain Following

`waiting` starts at zero. Despite its name, it will count all unresolved ground/harvester states, including `Inside` and `Running`, not just `Waiting`. The update calculates the current worm position and harvester forward/right before walking through all crew.

An `Inside` person's current position follows the current moving harvester exit. Their original destination is not updated until release. A `Running` person forms a displacement to destination and removes its vertical component, so movement is horizontal. Available walking time is $\min(dt, \max(0, \text{elapsed} - \text{released}))$. This prevents a newly released person from walking the entire `dt` when only a small final part of the step occurred after release.

At walking speed 3.8, a person reaches their destination when remaining distance is at most $\text{walkDt} * 3.8 + 0.00001$. The tiny extra tolerance avoids floating-point near-arrival jitter. Arrival snaps position to destination and changes the state to `Waiting`. Otherwise movement is normalized horizontal displacement times walking distance. Zero-distance people take the arrival branch rather than dividing by zero.

Every person then has their y set to terrain height at their current x/z, regardless of state. That includes `Aboard`, `Safe`, and `Lost` people. This header does not physically attach an `Aboard` person's stored position to the aircraft or move a `Safe` person's stored position to base. Their states and counters carry those meanings; their stored positions can remain at old pickup points, which the renderer can choose not to draw for those states.

Game Lines 251-259: Crew Hazard Windows and Unresolved Count

`outside` means the state is `Running` or `Waiting`. Danger radius is 16 before breach, 32 from breach until attack time 12, and 44 at attack time 12 and later. Separately, `activeWorm` is true before breach only after elapsed time is strictly greater than eight, or after breach only when attack time is strictly greater than three and strictly less than 18.

An `Inside` person is lost when attack time is at least 12, independent of their distance and independent of `activeWorm`. An outside person is lost when the worm is active and their horizontal distance is strictly less than the current radius. At the exact radius they are not lost by that test. The state changes to `Lost` and the loss counter increments once. On future updates that person is no longer `Inside` or `outside`, so the same local loss is not counted again.

The actual outdoor windows are therefore: no pursuit danger through exactly elapsed eight; radius 16 after eight and before breach; no outside danger from breach through exactly attack three; radius 32 after attack three and before 12; radius 44 from attack 12 until just before 18; and no local outside danger at 18 or later. `Inside` swallowing remains active after 12. The interval between breach and attack three is a real rule gap, not an omitted continuous hazard.

After those possible transitions, the update counts every remaining `Inside`, `Running`, or `Waiting` person into `waiting`. `Aboard`, `Safe`, and `Lost` do not contribute. This local count is used by the natural-completion branch and is decremented immediately if someone boards later in the same update.

Game Lines 261-277: Prompts and Unloading

The initial prompt is `HARVESTER FLEEING / RESCUE AMBER GROUPS` before breach or `WORM BREACH / CLEAR THE HARVESTER` at and after breach. Actual low-flight status is `g_ornPos.y-ground <= 11`; the desired altitude alone is not enough. Steady means speed strictly below six. At base means horizontal distance strictly below 14.

A full cabin overwrites the prompt with `CABIN FULL / RETURN TO CYAN BASE`. At attack 12 or later, that is overwritten with either `HARVESTER LOST / DELIVER SURVIVORS TO BASE` if anyone is aboard, or `HARVESTER LOST / RESCUE REMAINING GROUPS` otherwise. Prompt order matters: these are assignments, not independent UI messages.

If at base with at least one occupant, the prompt becomes `HOLD SPACE / UNLOAD SURVIVORS`. Only simultaneous Space, low status, and steady status increase unload progress, by $dt/1.2$. Completion at progress one means a continuous eligible interval of about 1.2 seconds. Every Aboard person's state changes to Safe, rescued increases by the entire cabin count, aboard becomes zero, unload resets to zero, and best updates to the maximum banked score.

If any unloading requirement fails, progress resets, rather than pausing and preserving its partial value. Being outside base or having no cabin occupants also resets it. No fractional score is banked before completion. A large step that exceeds the interval unloads once and discards extra progress; it does not calculate repeated unload transactions.

Unloading happens before nearest-person pickup. In an unusual fixture with waiting people at base, an update may unload a previous occupant and then start or complete a new pickup. The code does not declare the base a pickup-free area. Also, later pickup prompts can overwrite the unloading instruction even while unload progress is being processed, so prompt text is not an exclusive state-machine representation.

Game Lines 278-297: Target Selection and Pickup Dwell

The pickup search starts with index -1 and radius 12, scans every crew index, and skips everyone not Running or Waiting. A candidate replaces the nearest only if its horizontal distance is strictly smaller than the current best. A person exactly 12 units away is not selected, and equal-distance ties favor the first encountered index.

Changing target resets pickup progress immediately. The current target field then becomes the selected index. A valid target and an aboard count below eight allow the pickup block. If measured clearance is too high, the prompt says `T00 HIGH / HOLD SPACE TO LOWER WINCH`; otherwise it says `HOLD SPACE / HOVER TO WINCH CREW`. This text does not separately report excessive speed, although speed still controls eligibility.

With Space, clearance at most 11, and speed below six, pickup adds $dt/0.42$. At one or more, that single person becomes Aboard, aboard increases, unresolved waiting decreases, progress resets, and target resets to -1. The next frame must search again. Losing eligibility, having no target, or having a full cabin resets progress.

The 0.42-second requirement is per person. It is not enough to spend that total near multiple changing targets, since each target switch loses partial progress. Boarding does not increase rescued or best. The cabin limit is checked before boarding, so a correct counter never goes above eight.

Only one person can board per call, even with a very large dt. Extra progress is discarded rather than carried to the next person. Thus dwell behavior under coarse steps is quantized, and exact angular smoothing should not be confused with a guarantee that every gameplay outcome is identical under arbitrary dt. The test suite mainly uses fine updates and separately tests the scheduled-release boundary logic.

Game Lines 298-307: Aircraft Collision, Natural Completion, and Timeout

Aircraft approach collision requires pre-breach attack time, elapsed strictly greater than eight, horizontal distance to the worm strictly below 18, and aircraft y strictly below `worm.y+22`. Breach collision requires attack strictly greater than three and strictly less than 15, horizontal distance strictly below 24, and y strictly below `worm.y+40`.

These heights are relative to terrain at the worm, not necessarily terrain under the aircraft. At coincident x/z they are the same terrain height, which the height-envelope tests use. At separated points on a dune they can differ. Aircraft and crew therefore have different radii and different post-breach end times: aircraft local breach danger stops at 15, outside crew danger stops at 18.

If either aircraft-hit condition is true, every person other than Safe or already Lost becomes Lost and increments the loss total. This includes remote people and cabin occupants, not just those near the crash. Aboard is set to zero, `planeLost` becomes true, the prompt becomes ORNITHOPTER LOST IN THE WORM'S MAW, and `finishMission()` enters debrief. Banked Safe people survive and retain their score.

The alternate finishing branch runs only if there was no aircraft hit. It triggers when unresolved waiting is zero and aboard is zero, or when attack time is at least 60. Any remaining nonsafe/nonlost people are then marked Lost, aboard is cleared, and finish is called. The natural condition does not require rescued to equal 36: a mixture of delivered and lost people can satisfy it.

Timeout is 60 seconds after breach, making a first-wave total deadline of 270 seconds and a floor-wave deadline of 210 seconds. The function does not set `planeLost` for timeout. Because unloading and pickup precede this branch, a delivery that completes on the update reaching the timeout can bank its occupants before unresolved people are lost. Conversely, any person newly picked up on that same frame without a completed delivery is still unbanked and is lost.

No separate penalties are applied for rock contact, leaving the map, or hitting the harvester in this header. Map edges clamp movement, obstacle proximity requests clearance, and the worm alone supplies explicit aircraft loss. Pausing freezes elapsed time, so deadlines are simulation-time limits rather than unavoidable wall-clock limits.

Test Harness and Fixtures

Test Lines 1-13: Dependencies, Namespace, and Result Fields

The test header also uses `#pragma once`. Its comment says to include it after the game header and that these tests never initialize GLFW or call OpenGL. They still use GLFW key constants and the globals supplied by the surrounding program. This is a mission-logic test suite, not an independent replacement for all application initialization.

`<iostream>` supplies console streams and `<limits>` supplies infinity and NaN values. The namespace `arrakis_tests_detail` contains the small harness and reusable setup helpers without putting their short names directly into the global namespace.

`Results.current` is a borrowed `const char*` case-name pointer, initially the empty string. `cases`, `failedCases`, `checks`, and `failures` are integers initially zero. A case is an entire named scenario; a check is one Boolean assertion. Several checks can fail within one case. Consequently `failedCases` and `failures` need not be equal.

Test Lines 15-32: Every Results Method

`check(condition, message)` always increments the check count. If condition is false, it increments failure count and writes `[FAIL]`, the current case name, a colon, the supplied explanation, and a newline to standard error. It does not throw, abort, or return early, allowing a case to collect additional failures.

`run(name, test)` is a function template accepting a callable of any suitable type. In this file those callables are lambdas. It stores the case name, increments `cases`, snapshots the existing failure count, and calls the callable. If the count has changed afterward it increments `failedCases`. It prints `[PASS]` or `[FAIL]` followed by the name to standard output according to whether that case added failures.

An earlier failure does not automatically fail every later case, because comparison is against the per-case snapshot. The harness does not catch exceptions, measure test durations, isolate process state, or stop after the first failure. Helpers reset globals between scenarios. A serious setup failure could still lead to later invalid indexing because `check` is not a protective assertion that terminates execution.

Test Lines 34-40: Near Comparison and State Counter

`near(a, b)` checks whether absolute difference is strictly less than 0.001. It uses absolute tolerance, not a percentage or a relative error. Exactly 0.001 is outside the accepted interval. NaN differences do not satisfy the comparison.

`count(state)` starts at zero, loops over all mission crew by constant reference, adds one for each exact state match, and returns the count. It derives population information from individual states rather than trusting score/cabin/loss counters, which makes later reconciliation meaningful.

Test Lines 42-55: Fresh State and Fine-Grained Advancement

`fresh(start=true)` clears every Boolean key in the key array, centers hover, zeros stored turn rate, replaces the mission with defaults, clears actual boost status, and resets wing phase. It then calls `resetMission(start)`. Unlike an ordinary retry, this fixture deliberately discards a previous best and wave because the default mission was installed first. The revision counter and audio state are affected by reset in the normal way.

`advance(seconds)` chooses `max(1, ceil(seconds*120))` update steps and calls `updateMission(seconds/steps)` for each. For positive durations this produces steps no longer than approximately 1/120 second. It always calls the updater at least once, even for zero seconds. Tests sometimes directly call the updater instead when an exact coarse interval or boundary is the subject of the scenario.

The helper is not a real-time wait and does not sleep. Advancing 100 seconds in title or pause simply executes many immediately returning simulation calls. Negative or nonfinite input is not its intended use; its integer conversion and update semantics do not provide general validation.

Test Lines 57-70: Hover Teleport and Staging Point

`hover(position, altitude=6)` is explicitly a teleport fixture, not autopilot. It replaces the passed position's y with terrain height plus the requested altitude, writes aircraft position, clears velocity and speed, centers hover and turn rate, and sets desired altitude. It does not clear keys, reset mission time, or change crew states.

`staging()` returns the first crew member's destination when crew exist, otherwise the current harvester position. It does not find the nearest unresolved member. In the compact fixture the first destination is a useful common pickup area even after that first person becomes Aboard or Safe, since their stored destination remains there.

These helpers isolate state transitions from route navigation. A test that uses hover demonstrates requirements at a chosen location but does not prove the player can fly there quickly enough. The later input-only case addresses that distinct limitation.

Test Lines 72-99: Compact Ready Crew, Collection, and Delivery

`readyCrew()` begins with `fresh()`. It chooses a terrain-height center at x zero and z -10. Every group is marked released and receives that same center. For each crew index *i*, the person becomes Waiting and is placed at center plus $(0.6 * (i \% 6), 0, 0.6 * (i / 6))$; integer division creates six rows and modulo creates six columns. The person's y is recalculated and destination becomes position.

All 36 therefore form a compact six-by-six grid. Original group identities, slots, and release values remain, but the release flags prevent normal scheduled spawning. This is a deliberate synthetic fixture. It must not be described as the actual spatial layout generated by the harvester's route.

`collect(occupants)` teleports to staging, holds Space, and advances `occupants*0.45` seconds. The 0.45 interval gives a small margin over each 0.42-second pickup. It does not directly set aboard or crew states, nor does it release Space afterward. Collection can still be limited by capacity or remaining eligible crew.

`deliver()` teleports to base, holds Space, and advances 1.3 seconds, a margin over the 1.2-second unload dwell. It likewise relies on real mission logic and leaves Space held. Tests that require Space released must explicitly change the key.

Test Lines 101-113: Every Reconciliation Assertion

`reconciled(r)` computes unresolved people by adding actual Inside, Running, and Waiting state counts. Its first check requires the vector to contain exactly 36 people. Its second requires actual Safe count to equal `rescued`; its third requires actual Aboard count to equal `aboard`; its fourth requires actual Lost count to equal `lost`.

The fifth check requires `rescued + aboard + lost + unresolved == 36`. In combination with the individual state-counter comparisons, this detects missing or double-accounted people. The sixth check requires the cabin count to lie inclusively between zero and eight. If phase is Debrief, a seventh conditional check requires unresolved to be zero and aboard to be zero.

The helper does not require every debrief to have 36 rescues, require best to equal rescued, inspect group identities, or compare stored cabin positions with the aircraft. It tests accounting invariants appropriate to both success and failure. Calls made while Flying produce six assertions; calls during Debrief produce seven.

Reset, Population, and Pickup Cases

Test Lines 115-140: Case 1, Reset and Title Do Not Advance

`runMissionTests()` imports the helper namespace locally and constructs a fresh `Results`. Each case is registered with `r.run` and a lambda capturing surrounding variables by reference. The first case calls `fresh(false)` to enter Title rather than active flight.

The checks at lines 121-126 require Title, wave one with breach time near 210, all four score-related counters at zero, all 36 people Inside, altitude near eight, and full boost near one. The combined counter check specifically includes best because `fresh` discards old records before reset.

The case snapshots aircraft position/yaw and harvester/worm positions. It sets the cursor to the right edge at midheight and holds D plus Space, then advances 100 seconds. Assertions at lines 133-138 require elapsed time still zero; aircraft position unchanged within 0.001 and wing phase near zero; unchanged yaw and zero smoothed turn rate; all crew still Inside with zero pickup; and both moving-world actors unchanged within 0.001.

These checks prove the update guard freezes title simulation even under nonneutral steering, movement, and winch input. They do not require `g_mouseHover` itself to stay zero, because cursor arithmetic is allowed to store hover while the simulation is inactive. The case closes with the six active/title reconciliation checks.

Test Lines 142-178: Case 2, Pause Freezes Mission and Resumes

After `fresh`, the case applies right-edge hover and advances seven seconds. This gives an already moving harvester and a first group in the evacuation process, making pause more meaningful than freezing an untouched initial state. It copies the entire mission, snapshots flight position, wing phase, yaw, stored turn rate, harvester/worm positions, and worm gap, then sets pause and holds W, Shift, and Space.

After 100 simulated seconds of attempted advancement, lines 155-158 separately require an unchanged elapsed clock; unchanged aircraft position and wings; unchanged yaw and stored turn rate; and unchanged boost plus pickup progress. Because pause returns before boost logic, contradictory boost/winch keys do not alter resources.

The first comparison loop initializes `crewUnchanged` from vector-size equality, then proceeds only while that flag remains true and the index is within the copied population. Each person must retain state and position within 0.001. The assertion at line 163 checks that accumulated Boolean. It does not compare every Evacuee field, such as destination, individually.

Lines 164-166 require unchanged harvester and worm positions, yaw, accumulated travel, and gap. A second short-circuit comparison loop checks group vector-size equality, then released flags and centers within 0.001. Line 171 checks its result. The case clears all keys, centers the mouse, unpauses, advances 0.1 second, and requires elapsed time to increase. Reconciliation then confirms the still-active population.

Test Lines 180-246: Case 3, Scheduled Groups and Fixed Clusters

The initial assertion requires exactly 15 groups. For each group, lines 186-187 check the repeating one-through-four size, release $6+7*i$, and an initially false release flag. The nested crew loop counts members with this group index. Each member must have a slot from zero through `count - 1` and the group's release time within near tolerance.

A bitmask records slots by setting `1u << slot` for slots zero through three. The group assertion requires both the correct member count and the mask `(1u << count) - 1`. Together these verify every expected slot is represented exactly once: a duplicate would consume one of the fixed number of members and leave a required slot absent. The accumulated count must total 36 and the last group must contain three.

The case records the last Inside person's initial position and the initial harvester position, then advances 5.99 seconds. It requires all 36 still Inside. A combined movement assertion requires that last person to have moved more than two

units, remain less than 15 horizontally from the current harvester, and the harvester itself to have moved more than two. This checks following rather than a fixed spawn position.

Advancing another 0.02 crosses the first release. The first person must be Running and exactly 35 remain Inside. The case records their current position, destination, and group center, then independently constructs the tangent, right vector, and exit at exactly time six. Lines 219-221 require center to equal scheduled exit plus 14 rightward units within horizontal tolerance 0.001, and the one-person destination to equal center horizontally.

Another 0.25 seconds must move that person by approximately $3.8 * 0.25 = 0.95$, with absolute movement error below 0.01. Another 5.74 seconds leaves elapsed near 12, before the second release at 13, and all 35 other people must still be Inside. Another 1.02 crosses that release: group one must be released and only 33 remain Inside.

Advancing 106 more seconds reaches a time at which all default groups have released and walked, but still before breach. The assertion requires 36 Waiting. Stored first destination and center must remain unchanged in full three-dimensional distance below 0.001. A loop then requires every person's horizontal distance to destination below 0.15 and their y near terrain height. The first and final group centers must differ by more than 20 horizontal units.

Finally, the first waiting position is snapshotted, five more seconds are advanced, and it must stay fixed within 0.001 while the harvester and worm continue. Reconciliation verifies all 36 remain unresolved but correctly counted. This case exercises actual scheduled evacuation rather than the compact fixture.

Test Lines 248-267: Case 4, Space Dwell and Eight-Person Capacity

The case uses readyCrew and teleports to staging. One second without Space must leave aboard zero. It then holds Space for 0.3 seconds, less than the pickup dwell, and requires aboard still zero but pickup progress positive.

Releasing Space for 0.05 seconds must reset progress to near zero. Holding it for 0.5 seconds must produce exactly one occupant and exactly one person in Aboard. Rescued and best must still be zero, proving boarding is not scoring.

After five additional seconds of eligible hovering, the capacity constant must equal eight and the cabin count must equal eight. The remaining 28 people must still be Waiting. This simultaneously checks repeated pickup, capacity enforcement, and preservation of ground crew once full. Reconciliation verifies cabin and population totals.

Test Lines 269-278: Case 5, Excessive Speed Blocks Pickup

The compact fixture is prepared, the craft is placed at staging, and Space is held. The case deliberately gives the aircraft a velocity of $(20, 0, 0)$ and runs one 0.05-second update. With Space damping at rate 12, it remains fast enough to exceed the six-unit threshold despite slowing.

The first assertion explicitly checks that setup still has speed greater than six. The second requires aboard zero and pickup progress near zero. Without the first assertion, a test could accidentally pass or fail after its injected velocity had decayed below the intended boundary. Reconciliation checks population consistency. This is not a sustained high-speed flight test; it isolates one invalid pickup frame.

Test Lines 280-294: Case 6, High Hover Must Lower Before Pickup

The aircraft begins at staging 35 units above local terrain. After 0.75 seconds without Space, aboard must be zero and desired altitude still near 35. The case then holds Space for 0.5 seconds.

Actual clearance must still exceed 11 after that initial lowering period, and aboard plus pickup progress must both remain zero. This distinguishes desired-altitude smoothing from actual y smoothing; merely pressing Space does not instantly satisfy clearance.

After two further seconds, measured clearance must be at most 11. At least one person must be aboard, while rescued remains zero. Reconciliation confirms no accounting change was mistaken for scoring. The scenario demonstrates eventual winch lowering, not a direct Q/E altitude-key test.

Test Lines 296-318: Case 7, Delivery Banks Only at Base

`collect(3)` must create exactly three unbanked occupants. The craft then hovers at base plus 15 x units and advances 1.4 seconds with Space still held by collection. Aboard must remain three, rescued zero, and unload near zero. This tests a point outside the strict 14-unit base radius, not the exact radius boundary.

At base, Space is released and 1.3 seconds passes; rescued must still be zero. Space is held for 0.6 seconds; rescued remains zero but unload becomes positive. Releasing it for 0.02 seconds resets unload to zero.

`deliver()` then supplies a fresh eligible dwell. The next combined check requires rescued three, best three, and no occupants. Exactly three people must be Safe and the phase must remain Flying because 33 unresolved people remain. Reconciliation checks that their states match all counters. This case separately tests location, key requirement, dwell, interruption, score banking, and continuation after a partial delivery.

Failure, Retry, and Completion Cases

Test Lines 320-347: Case 8, Swallowing Spares Remote Ground Crew

The case delays every group and every person's release to 1,000 seconds. It sets elapsed to breach plus 11.5 and updates the harvester, then makes person one Running exactly 40 x units from the worm with destination equal to position. People two and three become Waiting at base and base plus two x units. The other 33 remain Inside.

One 0.25 update reaches attack 11.75. No one must be lost and phase must remain Flying: the local person is beyond the 32-unit radius and Inside swallowing has not started. Because destination equals position, the Running local person can become Waiting during the crew loop; the scenario's key property is being outside at 40 units, not continued walking.

Another 0.25 reaches attack exactly 12. The assertion requires attack time near 12, losses 34, and no Inside people. Those losses are the 33 Inside people plus the outside person within the now-44-unit radius. Exactly two Waiting people must survive, phase remain Flying, and rescued stay zero.

After eight seconds, attack is 20 and local outdoor hazards have stopped. The craft is teleported to base and Space is held for one second. It must carry both survivors with losses still 34. `deliver()` must bank two and produce Debrief because nobody else remains unresolved. The seven debrief reconciliation checks prove all 36 are accounted for. The test explicitly disproves the assumption that swallowing automatically kills every waiting person anywhere in the world.

Test Lines 349-367: Case 9, Carried Crew Survive Swallowing

The compact fixture collects eight, and an assertion confirms that setup. Every non-Aboard person is changed to Inside and given a personal release time of 1,000. Group release flags remain true from the fixture, so these manually Inside people are not rereleased by the scheduled loop.

Space is released; elapsed is placed at breach plus 11.75; one 0.25 update reaches attack 12. Exactly 28 must be lost while eight remain aboard. Phase must still be Flying and rescued zero, demonstrating that cabin survival is not yet a banked rescue.

Reconciliation runs before delivery. `deliver()` then must produce Debrief, rescued eight, and best eight. A second reconciliation runs in the finished state. This separates ordinary crew swallowing from aircraft collision: the aircraft remains remote, so carried people are not automatically consumed with the harvester.

Test Lines 369-387: Case 10, Collision Preserves Banked Score

The fixture collects eight, delivers them, then collects eight more. An assertion requires rescued eight and aboard eight. Space is released, elapsed becomes breach plus four, and the harvester is updated. The craft is teleported to the worm and a 0.01 update triggers the active breach aircraft envelope.

Phase must become Debrief and cabin count zero. Losses must equal 28, while rescued and best both remain eight. The 28 are every unbanked person, including eight occupants and 20 ground people. The state reconciliation confirms the eight already Safe were not included in losses.

The case snapshots elapsed, advances ten more seconds, and requires elapsed unchanged and losses still 28. That tests both the debrief guard and protection against double-counting finished losses. This particular case does not separately assert `pPlaneLost`; the dedicated envelope case does.

Test Lines 389-409: Case 11, Extraction Timeout

After banking eight and carrying another eight, the aircraft is placed 20 x units from base, outside unloading radius, and Space is released. Every remaining Waiting person is placed at base plus (40, 0, 40), remote from the stopped worm. Elapsed becomes breach plus 59.75.

A 0.125 update reaches attack 59.875. Assertions require Flying, eight occupants, zero losses, and 20 Waiting people. Reconciliation verifies that the setup is valid just before timeout.

A second 0.125 reaches exactly 60. The next assertion requires attack time near 60 and Debrief. The final totals must be rescued eight, best eight, losses 28, and cabin zero. Timeout consumes both undelivered cabin occupants and unresolved remote ground crew, but not the banked eight. Final reconciliation verifies the complete accounting. The aircraft need not collide or set `pPlaneLost` for this ending.

Test Lines 411-440: Case 12, Retry Preserves Best and Clears Attempt State

The fixture collects and delivers eight, releases Space, places elapsed at breach plus 60, and calls `updateMission(0)`. The setup assertion requires Debrief and best eight. Zero dt is enough because the ending condition evaluates the already-set clock.

The case deliberately contaminates pause, boost, pickup, unload, target, velocity, hover, and stored turn rate. Values include boost 0.2, pickup 0.7, unload 0.4, target five, velocity (10, 0, 0), corner hover, and turn rate -50. It then calls ordinary `resetMission(true)`, not `fresh`, so preserving best is actually exercised.

The six subsequent checks require Flying, unpaused, wave one; best eight with current rescued/aboard/lost zero; elapsed and both dwell values near zero with target -1; full boost, altitude eight, and velocity length below 0.001; neutral hover, zero turn rate, and camera pitch 12; and aircraft position within 0.001 of base plus eight upward units with all 36 Inside.

Reconciliation checks the new population. The scenario does not claim retry clears keys or wing phase. Its assertions are restricted to state the reset actually restores and the camera default derived from those resets.

Test Lines 442-457: Case 13, Next-Wave Timer Floor

After `fresh`, the test writes best 17 and directly calls `finishMission`, then resets with both arguments true. Wave must become two with breach time near 200. Best must remain 17, phase Flying, and all 36 Inside.

An eight-iteration loop snapshots the current breach time and starts another next wave. Each iteration checks that the new threshold is no greater than the previous one and no less than 150. Afterward wave must equal ten and time be near 150. Reconciliation validates the final `fresh` population.

This directly exercises `reset`'s progression formula without playing every intermediate wave. It does not prove later waves remain fully rescuable before their shorter breach thresholds; the detailed input-only playability scenario uses wave one only.

Test Lines 459-490: Case 14, All 36 Through Real Crew State Flow

This case uses normal `fresh` and advances 120 seconds so all real scheduled groups release and walk. It first requires 36 Waiting. It does not use `readyCrew`, but it still uses teleport assistance for navigation.

banked starts at zero. The five-flight loop chooses `batch = min(8, 36 - banked)`, producing batches 8,8,8,8,4. For each person in the batch, a nested search starts with no index and infinite distance, scans actual Waiting crew, and picks the nearest to current aircraft position. If no target is found it breaks that inner collection loop rather than dereferencing -1.

Each selected position is reached with hover, Space is held, and 0.45 seconds are advanced. At the end of each batch, cabin must equal expected batch while rescued still equals the previous banked total. Reconciliation checks the load. Delivery then runs, banked increases by the expected batch, and rescued must equal that value with an empty cabin.

The phase assertion expects Flying for every banked total below 36 and Debrief exactly at 36. Reconciliation runs after each base visit. Final assertions require rescued and best 36, zero losses, 36 Safe, and elapsed before breach. This proves full successful state transitions are possible without altering the timer, but its instantaneous relocation does not by itself prove a physically flown route meets the deadline.

Input-Only Rescue Scenario

Case 15 is substantially larger than the other cases because it constructs a small test-side controller. The controller reads the world and emits Boolean key states. It is not player-facing autopilot shipped in the gameplay header. After its initial fresh, it does not teleport the aircraft, directly change velocity, set crew states, edit the clock, or shorten the deadline. All subsequent game-state transitions come from the actual updater.

Test Lines 492-504: Case 15 Setup and Finite-Vector Helper

The case begins with fresh and an assertion that wave is one and the breach threshold is near 210. The comments explicitly rule out hover, collect, and deliver assistance after reset. The mouse remains neutral, so aircraft yaw stays at its initial zero and world-aligned cardinal movement is available through the aircraft-relative keys.

The controller snapshots base and uses a constant dt of 1/120. steps, travelSteps, boostSteps, directionsUsed, and directionReversals start at zero. Steps count every update; travelSteps count updates performed inside flight-leg attempts; boostSteps count actual boost frames; directionsUsed is a bitmask; directionReversals count changes between positive and negative commands within a flight leg.

finiteState, clearOfGround, and neutralHeading start true and are accumulated as permanent success flags. Once one becomes false, later good frames cannot restore it. minimumClearance starts with actual initial aircraft y minus local terrain height. The finiteVector lambda checks all three components with std::isfinite, detecting NaN and either infinity.

The lambda objects capture the surrounding test variables as needed. A capture by reference means updates inside a lambda affect those original counters and flags, rather than independent copies. The later seconds lambda instead captures constant dt by value, since it only converts a tick count to display time.

Test Lines 505-529: Step Instrumentation and Every Observed Quantity

Before each game update, step records W as bit one, A as bit two, S as bit four, and D as bit eight whenever held. Bitwise OR preserves every direction ever used. It then calls updateMission(dt), increments total steps, and increments boostSteps only if the updater reports actual g_isBoosting.

Finite-state checks include every component of aircraft position, velocity, and base; aircraft yaw, pitch, roll, speed, and wing phase; mission elapsed time, breach time, desired altitude, boost, pickup progress, and unload progress; both hover axes; and stored mouse turn rate. A loop also checks every person's position, destination, and release time.

These checks are extensive but not literally every floating-point field in the mission. They do not test finite group centers/release values, harvesterTravel, harvesterYaw, or wormYaw in this lambda. The final assertion's wording says all flight and crew float state, and should be read according to this actual list rather than generalized to every object in the application.

Neutral-heading monitoring requires yaw near zero, stored turn rate near zero, and hover vector length below 0.001 on every substep. This checks that WASD translation never secretly aligns the nose with its movement direction. Ground monitoring computes actual clearance each time, requires it finite and at least 3 - 0.001, and updates the minimum encountered clearance.

Because these are cumulative checks performed after every update, they can catch a transient invalid frame even if final state later looks correct. They still sample at update boundaries; they do not test a continuous path between those

samples or compare the craft with rendered rock geometry.

Test Lines 530-550: Active Predicate, Flight-Leg State, and Braking

`active()` requires `finiteState`, phase `Flying`, and `elapsed` strictly before `breach`. The controller voluntarily stops at `breach` even though gameplay permits further extraction for 60 seconds. Thus a successful result is a pre-breach playability result, not merely a rescue before the final timeout.

`fly(target)` snapshots the current step count. It starts previous `X/Z` command signs at zero, per-axis pulse accumulators at zero, and `braking` false. Its while loop continues only while `active` and fewer than `12*120` updates have elapsed for this leg, limiting a leg to 12 seconds.

Each iteration calculates a target delta and horizontal distance. Braking becomes permanently true for the rest of the leg once distance is below `4 + speed/12`. The `speed/12` term approximates coasting distance under Space's rate-12 damping; the four-unit margin starts slowing early. Once braking is set it is not unset if the next distance grows slightly.

All keys are cleared before new commands are chosen. Space is held exactly when braking. Left Shift is requested only while not braking, distance exceeds 20, and boost is above 0.08. This gives a controller-specific energy margin above the game's 0.04 lock threshold.

The leg succeeds when horizontal distance is at most two and actual speed is below 0.5. It adds its elapsed updates to `travelSteps` and returns true. These tolerances are more restrictive than the actual pickup/base radii and speed-six dwell requirement, helping stabilize arrival. Because the return happens before this iteration's step, no extra update is needed solely to acknowledge arrival.

Test Lines 551-569: Boolean-Key Pulse Controller and Axis Projection

If still more than two units away, the controller estimates available speed as 2.8 in braking mode, otherwise 48 if Shift is requested or 28 if not. It selects damping 12 while braking or 5.5 otherwise. The estimated speed can differ from actual boost behavior if the game's lock rejects Shift, but the game remains the authority over motion.

It constructs `backward = -flightForward()` and aircraft right from the cross product. These form the horizontal axes for commands. Dot products project world-space position error and actual velocity onto each axis, so the controller still uses the declared aircraft coordinate system rather than writing `x/z` velocity directly.

The nested `axis lambda` takes error, velocity, a pulse accumulator by reference, and the negative/positive key constants. It predicts remaining error after coasting as `error - velocity/damping`. If the current absolute error is below one, or predicted error multiplied by current error is at most zero, it clears the accumulator and emits no key. The latter means estimated coast movement is sufficient to reach or cross the target on that axis.

Otherwise, it adds `min(1, abs(predicted)*(braking?2:4)/speed)` to the accumulator. When that accumulator reaches one, it presses the key corresponding to the sign of error and subtracts one. Smaller desired commands therefore become occasional one-frame key pulses. This expresses proportional control through Boolean keys, not through fractional keyboard values, position assignments, or velocity overrides.

For the right axis, negative means A and positive D. For the backward axis, negative means W and positive S. The reversed-looking W/S arguments are correct because the axis is backward, not forward. Diagonal pulses are still normalized by actual game logic. Pulse duty cycle and feedback influence the route, but all acceleration, braking, altitude lowering, boost consumption, and pickup remain ordinary updates.

Test Lines 570-590: Reversal Accounting, Leg Failure, and Space-Only Steps

Command X is D minus A; command Z is S minus W. Only nonzero commands are compared with their previous nonzero sign. If a previous sign exists and differs, `directionReversals` increments. Zero-input coasting frames do not erase the remembered sign. Each `fly` call initializes these memories anew, so an outbound D and a later return A are not counted as a reversal within one leg.

The controller executes `step()` after commands and reversal checks. If `active` becomes false or the leg budget expires before arrival, it adds that leg's steps to `travelSteps` and returns false. This ensures unsuccessful movement attempts

still contribute to reported travel time.

`holdSpace()` clears all keys, enables only `Space`, and performs one instrumented step. It is used for waiting, boarding, and unloading. It does not directly complete a dwell. The `seconds(ticks)` helper multiplies ticks by `dt` and rounds to the nearest millisecond using `round(value*1000)/1000`; that affects printed summaries, not simulated time.

Test Lines 591-617: Return Decisions, Banking Assertions, and Trip Output

The controller initializes completed flights, cluster visits, outbound/boarding timing counters, and a 15-group visit bitmask. Departure is the current total step count. In the main while loop, `outside` counts Running plus Waiting, and `allReleased` means no Inside people remain.

Return is chosen with a full cabin, or with a nonempty partial cabin when all crew have released and no outside people remain. The assertion at line 598 requires either a batch of eight or that final-survivor condition. It prevents intentionally inefficient early partial returns while people still await pickup.

The controller snapshots batch, banked score, and boarding-completion step, then flies to the captured base. A check requires successful arrival; if arrival failed it breaks out instead of entering an endless unloading loop. While still active and occupants remain, it calls `holdSpace`. The next assertion requires `rescued` to increase by exactly the original carried batch and `aboard` to become zero. Reconciliation verifies all individual states afterward.

Each completed trip prints its sequential flight number, outbound duration, boarding/waiting duration, return duration, unloading duration, batch size, total rescued, elapsed mission time, and total trip duration. It increments flights as part of that print expression. Departure then becomes current steps, outbound and boarding counters reset to zero, and `continue` begins the next main iteration.

These durations classify test-controller phases. They are not guaranteed to match exclusive physical activities: `Space` during braking can already begin pickup or unloading before `fly` reports settled arrival. The printed unloading interval after settled arrival may therefore be less than 1.2 seconds because some progress happened during the return approach. No assertion requires a fixed wall-clock duration from these print labels.

Test Lines 618-646: Selecting Released Crew and Visiting Every Cluster

If no return is due, a nearest-person search starts with index -1 and infinite distance. It scans only Running or Waiting people and selects strictly smaller horizontal distances. If none exist yet, `holdSpace` performs a waiting step, `boardingSteps` increases, and the controller retries. Early scheduled gaps therefore consume legitimate mission time.

For a selected person, the controller records group and chooses a fixed pickup point: destination for Running crew, actual position for Waiting crew. It does not chase the Running person's changing position every frame. It flies to that point, adds the leg to `outboundSteps`, asserts successful arrival, and breaks on failure.

Successful arrival increments `clustersVisited`. A group index between zero and 14 sets its bit in `visitedGroups`. Repeated visits increase `clustersVisited` repeatedly but do not create new bits, so the final bitmask is necessary to prove coverage of every group rather than merely many visits to a few groups.

After arrival, a loop holds `Space` while active, cabin is below capacity, fewer than 3×120 updates have passed at the cluster, and the originally selected person's state remains Running or Waiting. It stops when that person is boarded/lost, the cabin fills, the local three-second budget ends, or active fails. Other nearby people can also be picked up during these ordinary updates. Boarding timing accumulates after the loop, and the outer controller reevaluates the world.

This loop does not forcibly wait until an entire group is collected in one visit. A group can require repeated outer-loop selections. The complete-group coverage and full-load return conditions are validated by final assertions rather than assumed from the controller's intent.

Test Lines 647-666: Every Final Input-Only Assertion and Summary

All keys are cleared at the end of the controller. The first final check requires the accumulated finiteState flag, and the second requires neutralHeading throughout the route. The third requires the cumulative ground-clearance flag. These validate numerical safety, no unintended yaw, and the terrain floor across all sampled substeps.

The fourth requires directionsUsed == 15, meaning every W/A/S/D bit was exercised, plus actual boostSteps greater than zero. The fifth requires directionReversals zero. It means no individual fly leg changed its nonzero cardinal command sign on an axis; it does not forbid opposite directions on different outbound/return legs.

The sixth requires rescued 36, zero losses, and 36 Safe. The seventh requires Debrief, best 36, and no occupants. The eighth requires elapsed strictly less than 210 and the unchanged breach threshold near 210. These prove a completely banked, lossless first-wave finish before breach rather than a partially filled cabin at the deadline.

The ninth requires exactly five completed flights, at least 15 cluster arrivals, and visitedGroups equal (1u<<15) - 1. Those conditions establish visits to all 15 released groups and the four full eight-person loads plus final four-person load implied by capacity and total 36. Reconciliation supplies the seven debrief accounting checks.

The final print reports travel seconds, elapsed seconds, rescued out of 36, aboard, lost, flights, clusters, minimum clearance, and approach reversals. The case then closes. Output reports are diagnostics, not extra Boolean assertions. Exact numeric travel durations are determined by execution and should not be invented from this source alone.

Analytic Route and Hazard Cases

Test Lines 668-705: Case 16, Route, Heading, Breach Freeze, and Worm Gap

The first part begins with fresh and samples route times 0,6,25,60,104,150,210. For each, it independently constructs x and z from the documented sinusoidal formulas and terrain height. Its first assertion requires the route helper to match that expected three-dimensional position within 0.001.

It converts route yaw to radians, constructs negative-Z-model forward, and independently calculates the derivative tangent. The second assertion requires finite yaw and a dot product greater than 0.99999 between heading and normalized tangent. A unit-vector dot product near one means the directions nearly coincide, rather than merely having similar angle numbers modulo 360.

It calls updateHarvester(t). The third assertion requires current position to match expected within 0.001 and yaw difference, wrapped with remainder, to have magnitude below 0.001. That checks both the pure helpers and the state-mutating helper. Three checks are executed at each of the seven sampled times.

After the final sample, the case snapshots breach position, yaw, and travel, then calls updateHarvester at breach plus 50. A combined assertion requires all three unchanged, checking the clamp and zero additional travel beyond the endpoint. It does not compare accumulated travel with an exact analytic arc length.

The second part calls fresh again and sets previousGap to 221, larger than the initial expected 220. It samples 0,1,30,75,104,150,209,210,230 by assigning elapsed and updating the harvester. Expected gap is independently calculated as $220 - 202 * \text{clamp}(t/\text{breachAt}, 0, 1)$.

At each of nine times, one check requires gap near expected and no greater than the previous sampled gap. Another requires worm x/z to match current harvester minus expected gap in x within 0.001. A third requires stored wormYaw near 90 and worm y near its own terrain height. It then records the gap for the next monotonic comparison.

This is a geometry test using deliberate clock assignments. It proves the worm relation, monotonic sampled closure, terrain following, and fixed stored yaw. It does not move an aircraft through a route or test whether the worm model's independently animated pose matches every geometric point.

Test Lines 707-748: Case 17, Frame-Rate-Stable Scheduled Release

Empty reference vectors are created for crew and groups. The outer loop runs at 30,60,120 updates per second. Each frequency starts with fresh; an inner loop performs 30 simulated seconds of updates. Before each update, elapsed is explicitly set to (tick-1)/frequency, then the updater receives 1/frequency.

These clock assignments intentionally remove accumulated-float drift from this fixture. This test is about release pose and walking time at equal absolute endpoints, not a proof that a long real clock accumulates identically across frame rates. The source comment contrasts it with the previous controller, which never edits the real clock.

The first, 30-Hz run is saved as reference. At later frequencies, every crew member must have the same state, horizontal position within 0.01, and full destination within 0.001. Every group's released flag must match and center must be within 0.001. At time 30, groups scheduled at six,13,20,27 have released; later groups remain Inside. Comparing all 36 therefore covers both released and unreleased populations.

The next part tests a release-straddling coarse frame. Starting from elapsed 5.99, it updates the harvester and runs dt 0.02, ending near 6.01. It saves first-person position/destination and first group center. A second fresh setup starts at 5.75, updates the harvester, and runs dt 0.26, also ending near 6.01.

The final combined assertion requires the two first-person horizontal positions within 0.001 and destination plus center within 0.001 in full distance. Both frames allow only approximately 0.01 second of post-release walking, even though their total frame durations differ drastically. This directly validates `min(dt, elapsed-release)` and use of the scheduled route pose. It does not compare coarse pickup throughput, aircraft displacement, or the other crew hazards across arbitrary frame sizes.

Test Lines 750-774: Case 18, Pursuit Crew and Aircraft Envelopes

Case 18 contains four distinct setups inside one named run. The first delays every group and person release to 1,000, sets elapsed to 100 before the default breach, and updates the harvester. Person zero becomes Running at worm plus 15 x units; person one becomes Waiting at worm plus 17. Destinations equal their positions.

After dt 0.01, the first assertion requires person zero Lost, person one Waiting, and loss count one. That distinguishes the 16-unit pursuit radius. The second requires 34 still Inside and phase Flying, showing ordinary pre-breach pursuit does not swallow Inside people or end a remote aircraft's mission.

The craft is then teleported at the worm with altitude 30. After another 0.01, phase must remain Flying and planeLost false, proving it is above the 22-unit aircraft height envelope. Teleporting at altitude 21 and updating 0.01 must instead produce Debrief, planeLost true, and all 36 Lost. Reconciliation verifies that the earlier local loss was not counted twice when the crash lost everyone else.

The locations are set relative to the worm at setup, and the worm moves slightly in the following update. The chosen distances 15/17 and heights 30/21 have margins, so this is not an exact equality test for 16, 18, or 22. Aircraft y also passes through normal smoothing before the hit test.

Test Lines 776-795: Case 18, Early Breach Crew and Aircraft Envelopes

A new fresh setup again delays release and places elapsed at breach plus four. People zero and one become Waiting at worm plus 31 and 33 x units. The craft is placed at worm altitude 45, then dt 0.01 runs.

The crew assertion requires the 31-unit person Lost and the 33-unit person still Waiting, distinguishing the active 32-unit outdoor breach radius before swallowing. The phase assertion requires Flying, because the aircraft remains above the 40-unit height envelope.

The aircraft is then placed at worm altitude 39 and another dt 0.01 runs. A combined assertion requires planeLost and Debrief, demonstrating the active breach aircraft envelope at horizontal distance near zero and height below worm terrain plus 40. Reconciliation follows. This segment does not independently assert a specific final loss counter; the reconciliation checks actual Lost states against the counter.

Test Lines 797-822: Case 18, Exact Start and Retreat Boundaries

The third fresh setup delays release and sets elapsed exactly eight. The first person is manually Waiting at the current worm position. `updateMission(0)` must leave that person Waiting because pursuit activation uses elapsed greater than eight, not greater than or equal. A subsequent 0.01 update must mark them Lost and set loss count one.

The fourth setup resets again, delays releases, and places elapsed at breach plus 18. The first person is Waiting exactly at the worm; the aircraft is remote at base. A zero-dt update must yield 35 losses, one Waiting person, and phase Flying. The 35 Inside people are swallowed because attack is already at least 12, but outside danger has ceased because its upper bound is strictly less than 18.

Reconciliation confirms one unresolved survivor remains. This scenario highlights that the retreat boundary does not revive prior Lost people and does not stop the unconditional Inside-crew loss rule. The closing lambda brace ends the whole four-part case.

Cursor and Steering Cases

Test Lines 824-856: Case 19, Cursor Arithmetic and Resize

The case snapshots aircraft position, yaw, and elapsed after fresh reset. Center cursor (500, 250) in a 1000x500 window must produce hover length below 0.001.

The horizontal sample loop uses x values 440, 460, 500, 540, 560 with centered y. Each must give x hover near zero, including the two exact nominal deadzone edges. The vertical sample loop uses y values 220, 230, 250, 270, 280 with centered x; each y hover must be near zero. These are five assertions per loop, not a single check of one representative center.

At $x = 570$, horizontal hover must lie strictly between zero and one; at $x = 430$ it must lie strictly between -1 and zero. At the left window edge, hover must be $x = -1$ and $y = 0$; at the right edge, $x = 1$ and $y = 0$.

At (800, 100) the raw normalized coordinates are (0.6, -0.6). After deadzone, the assertion expects (0.48/0.88, -0.48/0.88) within near tolerance. Doubling coordinates and dimensions to (1600, 200) in 2000x1000 must preserve that vector within 0.001. The new center (1000, 500) must return neutral hover.

The final combined assertion requires aircraft position unchanged, yaw unchanged, elapsed unchanged, and stored turn rate still zero. Repeated arithmetic input changes do not simulate a frame. This case validates normalized behavior after resize, but it does not create or resize an actual GLFW window or test event callback coordinate scaling.

Test Lines 858-878: Case 20, All Invalid Cursor Scenarios

The case obtains quiet NaN and positive infinity from `std::numeric_limits<double>`. A local `Cursor` record stores two double coordinates and integer width/height. Its array contains 14 invalid inputs, each tested independently after reseeding active hover.

The four outside-window scenarios are $x = -0.01$, $x = 1000.01$, $y = -0.01$, and $y = 500.01$ in the original 1000x500 dimensions. Two NaN scenarios put NaN in x or y. Four infinity scenarios put positive or negative infinity in either coordinate. Four invalid-size scenarios use width zero, height zero, width -1, or height -1 with zero cursor coordinates.

For each array entry, the case first supplies valid right/top corner hover and requires its vector length above 0.5. It then submits the invalid input and requires both components finite and total length below 0.001. Thus there are two assertions for each of the 14 scenarios: active setup and safe clearing.

The reseeding is important. Without it, an implementation that merely ignored invalid input could appear correct after the first zeroed result. These checks ensure invalid input actively clears previous steering on both axes, without producing NaN. Accepted exact window edges are covered separately by Case 19, so slightly outside values here intentionally test strict rejection.

Test Lines 880-908: Case 21, Hover Turns Without Clicks and W Follows It

The outer loop runs side -1 and side +1. Each begins fresh, records position, sets left edge for negative side or right edge for positive side, and advances 0.5 second with no keyboard movement or mouse-click input.

The first assertion requires yaw times side below -1 and stored rate times side below -1: right produces negative yaw/rate, left positive. The second requires rate near $-side * 80 * (1 - \exp(-8 * 0.5))$, validating the exponential approach at the half-second endpoint. The third requires horizontal position unchanged within 0.001 and speed near

zero. The fourth requires forward.x times side positive and forward.z negative, proving the new nose points toward the hovered side while still generally facing negative Z.

The cursor is then centered and two seconds pass to damp residual turning. The case records settled yaw, forward, and departure position, holds W, and advances 0.5. The next assertion requires displacement length above one, normalized displacement dot settled forward above 0.999, and displacement.x times side positive. The final assertion requires yaw change from the recorded settled value below 0.001.

Both left and right scenarios therefore prove stationary yaw steering, the correct sign convention, no unintended translation from hover, forward movement in the newly chosen heading, and heading retention during centered forward flight. The method does not require any button press for mouse steering.

Test Lines 910-921: Case 22, Arrow-Key Stationary Backup

For side -1 and +1, each fresh setup records aircraft position and holds the corresponding Left or Right arrow for 0.5 second. A sign assertion requires yaw*side and $\text{stored turnRate*side}$ below -1, matching hover steering's sign.

A second assertion requires horizontal position unchanged within 0.001 and speed near zero. This confirms arrows rotate a stationary craft without injecting translational input. It does not separately test simultaneous mouse-plus-arrow saturation, both arrows held together, or Up/Down keys; those behaviors must be inferred only where the game expressions actually define them.

Test Lines 923-946: Case 23, Every Translation Key at Wrapped Headings

The key array is W, S, A, D. The heading array is 0, 90, -90, 179, -181, 359, 361. The outer loop independently constructs forward $(-\sin, 0, -\cos)$ and right $(\cos, 0, -\sin)$ for each heading. The inner loop performs all four keys, giving 28 combinations.

Each combination resets, assigns the chosen yaw, and first asserts `flightForward()` matches the independently calculated vector within 0.001. Expected motion is forward for W, reverse forward for S, right for D, and reverse right for A. After recording position and holding the chosen key for 0.5 second, it forms horizontal displacement.

The second assertion requires velocity length above one and normalized velocity aligned with expected by dot product above 0.999, plus displacement length above one and its normalized direction likewise aligned. The third requires wrapped yaw difference from the assigned heading below 0.001 and stored turn rate near zero.

There are three assertion calls per combination, or 84 total within this case. The unusual headings check equivalent angles around wrap boundaries: 179 and -181 represent the same direction; 359 and -1 would as well; 361 is equivalent to one. The yaw storage can wrap during an update without failing because comparison uses remainder. Reverse and strafe are explicitly verified not to turn the nose toward velocity.

Test Lines 948-962: Case 24, Centering Damps Inertia Rather Than Recentering Nose

The case steers right for 0.5 second, snapshots yaw and turn rate, centers the mouse, then advances 0.25. The first assertion requires the new stored rate near $\text{oldRate} * \exp(-8 * 0.25)$. The second requires yaw smaller than its previous value and rate still negative, demonstrating continued turn while inertia decays rather than an instant snap.

Two more seconds must reduce rate magnitude below 0.001. After recording that settled yaw, another 0.25 must change it by less than 0.001. A centered mouse thus means stop requesting turn, not aim the nose back to zero degrees. These four checks cover the release transient, eventual settling, and retained heading.

Test Lines 964-980: Case 25, Exact One-Second Turning at Three Frequencies

Two three-element arrays store yaw and rate. The frequency array is 30, 60, 120. Each run resets, applies right-edge hover, and calls the updater exactly frequency times with $\text{dt } 1/\text{frequency}$, simulating one second without the advance helper.

The rate assertion requires absolute error below 0.002 from $-80 * (1 - \exp(-8))$. The yaw assertion uses the exact one-second integral $-80 * (1 - (1 - \exp(-8))/8)$ and also requires error below 0.002. Two checks run at each

frequency.

After the loop, a final combined assertion requires 30-Hz yaw and 60-Hz yaw each within 0.002 of 120-Hz yaw. This is a seven-check case. It is strong evidence for the analytic angular integration under constant steering, but it does not show equivalent translational trajectories, roll animations, target switching, pickup totals under very coarse steps, or arbitrary changing-input schedules.

Camera Cases and Test Result

Test Lines 982-1006: Case 26, Every Camera Behind Heading

After fresh reset, headings 0, 90, -90, 179, -181, 359, 361, 720 are tested. The addition of 720 checks multiple full rotations, because trigonometric direction should be unchanged. For each heading, the case computes flight forward and aircraft right. It then tests vertical cursor positions 0, 250, 500 in a 1000x500 window, and camera modes 0, 1, 2.

That gives eight headings times three vertical inputs times three modes, or 72 combinations. For each combination, the offset and its horizontal projection are calculated. The first check requires all offset components finite and y positive. The second requires nonzero horizontal length and normalized horizontal offset dot forward below -0.999, proving the camera is directly behind rather than merely somewhere elevated.

The case computes `viewRight = normalize(cross(-offset, up))`, treating the direction from camera toward target as `-offset`. The third check requires its dot with aircraft right above 0.999. This ensures D/right movement is screen-right in the corresponding look-at orientation rather than visually reversed.

Exactly one mode-specific fourth check runs per combination. Mode 0 requires offset length near 40. Mode 1 subtracts $(0, 2.2, 0)$ before requiring length near 20. Mode 2 requires y near 100 and horizontal length near 26. The branch structure means each combination receives four checks, for 288 assertion executions.

This verifies helper geometry and screen-right basis, not an OpenGL image, projection matrix, camera-target offset used elsewhere, or a real mouse callback. Mode 2 is checked at all three vertical cursor positions even though its offset deliberately ignores camera pitch.

Test Lines 1008-1036: Case 27, Vertical Pitch Mapping, Orbit Clamp, and Both Reset Modes

The case begins centered and requires pitch 12. At the top edge, it records pitch and checks hover magnitude near one plus exact mapping to the clamped expression `12-hover.y*22`. At the bottom edge, it performs the corresponding check again. A fourth check requires the lesser of these pitches near 6 and the greater near 34.

With bottom-edge hover still stored, an orbit loop uses -100, 0, 15, 100. For each, it writes `g_camOrbitPitch` and checks pitch against `clamp(12-hover.y*22+orbit, 6, 65)`. Those inputs exercise extreme low/high clamping and intermediate adjustment. They demonstrate that the full 6-to-65 range includes orbit contribution, while mouse extremes alone span 6-to-34 under zero orbit.

The final loop runs `start=false` and `start=true`. Before each reset it installs right/top hover, stored turn rate -60, and orbit 35. Calling `resetMission(start)` must center both hover axes, clear turn inertia, and restore yaw zero. A second check requires orbit zero and derived camera pitch 12. These are two checks per reset mode.

The scenario proves camera and steering state restoration for both title and playing resets. It does not explicitly check their phase values here because title and flying phase selection are already checked elsewhere. There are 12 assertion executions in this case: four initial mapping checks, four orbit checks, and four reset checks.

Test Lines 1038-1041: Console Summary and Process Result

After all 27 named cases, the function prints a summary containing successful cases over total cases, total checks, and total failures. Successful cases are calculated as `cases - failedCases`, not as checks minus failures. The checks total depends on repeated loops and, for the input controller, the route's visited clusters and return legs.

It returns zero when failures is zero and one otherwise. A caller can use that result as an executable exit code for automation. The code does not return the number of failures or use different exit codes for different cases.

Standard-output case labels and diagnostics plus standard-error assertion messages provide the human-readable detail.

This chapter explains what the suite checks; it is not an execution log or a claim that a build was run while writing the documentation. The build-and-run documentation describes the actual test invocation and any independently observed run results.

Important Limits

The implementation and tests are deliberately small and deterministic. Understanding their actual boundaries is as important as understanding the successful scenarios.

- Best score is process-local mission memory here. Reset preserves it, but this header provides no persistent save file.
- Aboard and Safe are logical states. Stored crew positions are not updated to aircraft or base coordinates when those states change.
- The unresolved counter called `waiting` includes `Inside` and `Running`, not merely `Waiting`. Natural completion requires no unresolved people and no cabin occupants, not a special victory flag.
- Harvester movement and release destinations use analytic route formulas. Harvester accumulated travel is sampled chord length, and translational position integration is not an exact continuous integral.
- Angular rate and yaw have an explicit exponential solution under a constant steering command. This does not make all controls, animation values, dwell transactions, or hazards invariant under arbitrarily large `dt`.
- Pickup and unload progress reset on interruption. Pickup additionally resets when nearest target changes. One update boards at most one person, and excess progress is discarded.
- Local crew hazard, local aircraft hazard, `Inside` swallowing, and final timeout are four distinct rules with different radii and time intervals.
- Clearance assistance is not a collision model for rendered rocks or the harvester. The only explicit aircraft-loss checks in this header are worm envelopes.
- Mouse invalid-input tests cover finite and nonfinite cursor data, but gameplay does not similarly validate every externally supplied `dt` or every externally mutated global.
- Most transition tests use deliberate fixture mutations or teleportation. The input-only controller is the specific case proving an actual key-driven complete first-wave rescue before the unchanged breach timer.
- The controller's no-reversal assertion applies within each flight leg. Opposite commands on separate return legs are expected and are exercised.
- Headless mission tests do not verify rendered pixels, model orientation in a screenshot, graphics driver behavior, real-time audio playback, window callbacks, or asset loading.
- Later waves have shorter timers, but the exhaustive input-only rescue scenario establishes full pre-breach completion for wave one, not every difficulty wave.

Coverage Reference

The game explanation covers original lines 1-307, including both enumerations, all three structures, six crew states, three mission phases, every default field, six game globals/constants, all eight rock sites, every helper, both reset loops, tank records, finish behavior, and every update branch. The headings divide the file into source-order ranges so a reader can match each nonblank line to its explanation.

The test explanation covers original lines 1-1041. It explains the namespace and dependencies; all five `Results` fields; both `Results` methods; `near`, `count`, `fresh`, `advance`, `hover`, `staging`, `readyCrew`, `collect`, `deliver`, and `reconciled`; all 27 named cases; every test-side loop and helper `lambda`; the individual scenario assertions and repeated assertion families; and the final summary and return value.

For the long input-only case, source ranges 492-504, 505-529, 530-550, 551-569, 570-590, 591-617, 618-646, 647-666 separate setup, instrumentation, controller decisions, keyboard pulse conversion, movement accounting, delivery, crew visits, and final assertions. For the combined worm-envelope case, ranges 750-774, 776-795, 797-822 distinguish pursuit, early breach, and exact activation/retreat boundaries. These subdivisions preserve complete coverage without hiding complex test logic inside a single unexplained case title.

Chapter 5: The Rescue HUD and the Procedural Sandworm

Reading This Chapter

This chapter explains all of `arrakis_hud.h` and `arrakis_worm.h`, including their declarations, constants, helper functions, loops, conditions, rendering calls, failure paths, and cleanup. The HUD is the two-dimensional information layer drawn over the game. The sandworm is a three-dimensional object built from mathematical surfaces rather than loaded from a model file. Their purposes are different, but both turn game state into visible geometry.

All source references below use the original root-level files read for this chapter: `arrakis_hud.h`, lines 1-552, and `arrakis_worm.h`, lines 1-360. Their final project paths are `src/arrakis_hud.h` and `src/arrakis_worm.h`; the original references identify the same code after relocation. The explanations are not substitutes for the source appendix: they describe what the code means and why its operations are arranged this way without reproducing the complete source listings.

For a beginner, three distinctions are important. A value in a C++ structure is ordinary CPU data. A VBO is an OpenGL buffer containing data for the GPU. A shader is a small program that runs as part of drawing on the GPU. Generating a triangle in a CPU vector does not itself put a pixel on the screen; the program must eventually upload the vector and issue a draw call. Likewise, moving a mathematical centerline does not automatically update a worm mesh already stored on the GPU; the changed vertices must be sent again.

The HUD Header and Its Input Contract

Header Guard, Includes, and State Structure

****Source:** `arrakis_hud.h`, lines 1-28.**

Lines 1-2 start an include guard named `ARRAKIS_HUD_H`. The first inclusion defines the name and processes the contents. Later inclusions in the same translation unit skip the protected contents, avoiding duplicate declarations. The matching end directive is at line 552. The guard is a compile-time device; it is unrelated to whether OpenGL resources have been initialized at runtime.

The includes in lines 4-12 supply the facilities used throughout the header. GLAD supplies OpenGL types, constants, and loaded function entry points. GLM supplies vectors. `<algorithm>` provides clamping, minimum, and maximum. `<array>` provides fixed-size arrays for glyph rows and saved capability state. `<cmath>` supplies finiteness tests, rounding, and trigonometry. `<cstdint>` provides `std::size_t` and `offsetof`, which are important for buffer byte sizes and vertex attribute offsets. `<cstdio>` provides bounded formatted output and diagnostic printing. `<string>` provides owned strings and conversions. `<vector>` provides resizable arrays of geometry and markers.

`RescueHudState`, opened at line 14 and closed at line 28, is a snapshot of information to display. It does not run the mission, advance the timer, move the aircraft, or change crew states. The caller fills it from the game and passes it to the HUD. Its member initializers make an unmodified snapshot internally usable, but they are defaults rather than a second source of gameplay rules.

width and height default to 1280 and 720. These are framebuffer pixels, not necessarily the logical window dimensions reported by an operating system. On a high-density display, a window can have more framebuffer pixels than screen-coordinate units. The HUD uses these values for its viewport and derives a separate layout canvas from them.

Line 16 specifically explains `waiting`: it includes crew in both Running and Waiting states who are outside the harvester, not workers who are still inside. This matters because the UI later labels that count SAND; it is not merely the number of stationary people. Line 17 declares seven integers. `rescued` is the count secured by delivery to base and initially zero. `aboard` is the count in the aircraft, initially zero, and is visually compared with eight seats. `waiting` is the outside count just described. `lost` is the number no longer rescueable. `total` defaults to 36, the mission population displayed beside the secured count. `best` stores the record used on the results screen. `wave` starts at one and

identifies the mission or wave. All seven are numbers supplied by the caller; the HUD does not reconcile contradictory counts.

Line 18 declares `remaining`, initially 210 seconds; `altitude`, initially zero and displayed in meters; `speed`, initially zero; and `boost`, initially one. `Boost` is drawn as a normalized meter, so one means a full displayed bar. Line 19 adds `missionDuration`, initially 210, as the denominator for the pre-breach timer bar; `pursuit`, initially zero, as a normalized threat bar; `wormDistance`, initially 220, as the displayed range; and `extractionRemaining`, initially 60, as the post-breach countdown. A changing countdown and its total duration are different quantities: without the denominator, a progress meter could not tell what fraction remains.

Line 20 supplies `inside`, initially 36, and `releasedGroups`, initially zero. The first means crew still in the harvester; the second means groups released so far. Line 21 supplies `pickupProgress` and `unloadProgress`, both initially zero, and `fps`, initially 60. The two progress values drive the action message and shared action bar. FPS is diagnostic frame-rate information. Line 22 supplies a heading in degrees, initially zero, used only to rotate the player marker on the north-up radar.

Line 23 contains four booleans. `title` initially true requests the introduction overlay. `paused` requests the pause overlay. `ended` requests the result overlay and takes precedence over the title flag there. `muted` changes the telemetry text and color; it does not itself mute audio. The default false values for the last three mean that a default state shows the title screen rather than a paused, ended, or muted mission.

`prompt` in line 24 is an initially empty string. It can override the normal action instruction, and one exact prompt is also recognized when choosing the failure text on the result screen. Line 25 initializes five two-dimensional positions to zero: `player`, `harvester`, `base`, `worm`, and `pickup`. The radar interprets each used vector as ground-plane coordinates. `pickup` is declared but is not referenced by any drawing function in this header; describing it as a visible marker would be inaccurate. `crewMarkers`, in line 26, is a variable-length list of ground-plane crew markers. The header draws every supplied entry without deciding which crew qualify. Finally, `attackTime`, initially -1 at line 27, distinguishes approach from an attack that has begun. The HUD uses only whether it is at least zero; it does not implement the worm's detailed attack phases.

Rendering Preconditions and Internal Namespace

****Source: `arrakis_hud.h`, lines 30-34 and 454.****

The comments in lines 30-33 define the intended environment: a current OpenGL 3.3 core context, loaded GLAD entry points, framebuffer-pixel dimensions, and one owning context until cleanup. Creating or deleting OpenGL objects without the correct current context is outside that contract. A static CPU resource holder does not make GPU object names portable between arbitrary contexts.

The comments also describe the drawing function's state isolation. It saves and restores the program, VAO, array-buffer binding, viewport, polygon mode, write mask, blend setup, and selected enable flags. It does not switch the caller's framebuffer or texture bindings. This means the HUD is drawn into whichever framebuffer the caller has already bound. It is not a routine that automatically finds the screen framebuffer. Nor is the comment a promise to snapshot every possible OpenGL setting: only the state actually saved by `GLState` receives explicit restoration.

Line 34 opens `arrakis_hud_detail`, and line 454 closes it. Keeping implementation helpers in a named internal namespace prevents common names such as `text`, `bar`, and `Color` from colliding with unrelated names in the surrounding program. The three public lifecycle functions after the namespace form the intended entry points.

HUD Data, Colors, and Formatting

Color Palette, Vertex Layout, and Shared Resources

****Source: `arrakis_hud.h`, lines 36-52.****

`Color` is four floating-point components: red, green, blue, and alpha. RGB controls the tint; alpha controls how strongly the fragment contributes when blended over the existing scene. All palette components are expressed on a zero-to-one scale. The constants are `inline constexpr`, so they are compile-time values that can be defined in a header without

ordinary multiple-definition problems.

bone is (0.91, 0.89, 0.82, 1.0), a warm nearly white main text color. muted is (0.59, 0.61, 0.58, 1.0), used for secondary text. cyan is (0.36, 0.85, 0.86, 1.0), connecting the aircraft, safe base, and rescue progress. amber is (0.98, 0.65, 0.27, 1.0), used for crew and warnings. white is pure opaque white. threat is (0.98, 0.36, 0.27, 1.0), the warmer red-orange worm and pursuit color. black is (0.018, 0.025, 0.028, 0.84): it is a very dark panel background that still permits some scene contribution. edge is (0.42, 0.47, 0.46, 0.25), a faint translucent border and empty-bar color.

The HUD's Vertex at line 45 is not the scene mesh's position-normal-UV vertex. It has exactly six floats: pixel-space x and y, followed by r, g, b, and a. Every triangle vertex carries its own color. The simple HUD shader needs no normals, texture coordinates, light calculation, or font atlas.

Resources in lines 46-51 owns program, vao, and vbo, initially zero to mean no object has been created. canvas, initially -1, is the uniform location for the two-dimensional layout size; a uniform location is not an OpenGL object name. capacity, initially zero, counts allocated GPU buffer bytes, not vertices. vertices is the CPU-side batch of all triangles for the current composition. Its vector capacity is distinct from the GPU byte capacity.

resources() in line 52 returns a reference to a function-local static Resources. The object is created once and shared by these inline helpers. Returning a reference avoids copying its object names and vector. This is convenient for a single-context HUD, but it is not a collection of per-window or per-context resources. The static object's ordinary destruction also does not replace explicit OpenGL cleanup.

Finite Values, Counts, Rounded Measurements, and Clocks

****Source: arrakis_hud.h, lines 53-66.****

finite(v, fallback) returns v when std::isfinite accepts it; otherwise it returns the fallback, zero unless specified. It screens out both infinities and NaN. This prevents malformed measurements from turning into invalid positions or unreadable timer calculations. It does not clamp large finite values by itself.

unit(v) first replaces a non-finite value with zero, then clamps the result between zero and one. Bars can therefore receive values below zero or above one without drawing negative widths or filling beyond their background. number(v) converts the greater of zero and the integer argument to a string. Negative counts become 0; positive counts are not otherwise limited. The parenthesized (std::max) syntax also prevents an unfortunate function-like max macro from matching the name on platforms where such macros are present.

decimal(v) creates a 48-byte local character array, clamps a finite-or-zero value to the interval -99999 through 99999, and formats it with %.0f. Despite the function name, the displayed result has zero fractional digits. It rounds according to formatted floating-point output rather than truncating with an integer cast. The clamp limits the text width, and the bounded snprintf receives the full buffer size. Returning out constructs an owned std::string, so no pointer to a dead local array escapes.

clock(v) uses a different policy. It clamps to 0-5999, rounds upward with ceil, and casts the result to an integer number of seconds. Thus a positive fraction of a remaining second continues to display as one rather than immediately becoming zero. Integer division by 60 obtains minutes; remainder modulo 60 obtains seconds. %02d:%02d prints each part with at least two digits, producing values from 00:00 through 99:59. The 16-byte array comfortably holds this representation. A NaN or infinity becomes 00:00, because the default finite fallback is zero. These helpers sanitize display, not game state: they never modify the original snapshot.

Preserving OpenGL State

The Saved-State Structure and Constructor

****Source: arrakis_hud.h, lines 68-90.****

GLState is an automatic scope guard. Its constructor reads the caller's settings before the HUD changes them; its destructor restores those settings when the drawing function leaves scope. This pattern is often called resource acquisition is initialization, or RAII, even though here the managed resource is a restoration obligation rather than a

newly allocated buffer.

The integer fields in line 69 hold the active shader program, bound vertex array, bound array buffer, four viewport numbers, and two polygon-mode values. The viewport entries are origin x, origin y, width, and height. Line 70 stores four blend factors, separately for RGB and alpha, and two blend equations. Line 71 stores the four color-write booleans, one each for red, green, blue, and alpha. Preserving the mask matters because a previous render pass might intentionally have disabled color writes.

The fixed capability array in lines 72-74 names ten switches. Blending combines HUD fragments with the scene. Depth testing could reject overlay pixels based on three-dimensional depth. Face culling could discard triangles because of their winding. Scissoring could clip the HUD to an old rectangle. Stencil testing could mask it according to a previous pass. Rasterizer discard could prevent all fragments. Color logic operations could replace normal blending with bitwise operations. Sample alpha-to-coverage, sample coverage, and sample alpha-to-one could alter multisample behavior. The corresponding ten-element enabled array starts value-initialized and then stores each switch's actual incoming state.

Lines 77-88 query each scalar or array into its matching member using `glGetIntegerv` or `glGetBooleanv`. These queries do not intentionally change the state they inspect. The loop at line 89 visits every capability index from zero to one less than `caps.size()` and records `glIsEnabled(caps[i])`. The shared index ties each enum to the boolean that will later restore it; no capability is inferred from another one.

Destructor Restoration and Non-Copyability

****Source: `arrakis_hud.h`, lines 91-107.****

The destructor rebinds the old program, VAO, and array buffer in lines 92-94. The explicit casts convert the queried integer object names back to OpenGL's unsigned object type. It then restores all four viewport values. OpenGL core contexts use one polygon mode for front and back faces, so line 97 restores `polygon[0]` through `GL_FRONT_AND_BACK`; the comment at line 96 explains why it does not separately restore two independent face modes.

Lines 98-100 restore the separate RGB and alpha factors, separate equations, and per-channel write mask. The loop in lines 101-103 checks each saved boolean. A true value calls `glEnable` for that capability; a false value calls `glDisable`. This is stronger than blindly disabling blend after the HUD: if the caller had blending enabled, blending remains enabled afterward with the original factors.

The deleted copy constructor and assignment operator in lines 105-106 prevent accidentally copying a guard and creating two restoration obligations for the same old state. The closing brace and semicolon complete the type at line 107. This guard does not save buffer contents, uniforms inside programs, framebuffer bindings, textures, or every obscure rendering option. The HUD does not need to change the framebuffer or textures, and its canvas uniform belongs to its own program. Its buffer uploads likewise target its own VBO. Restoring bindings is not the same operation as undoing those intentional resource updates.

Turning HUD Shapes Into Triangles

Shader Compilation With Failure Cleanup

****Source: `arrakis_hud.h`, lines 109-124.****

`shader(type, source)` receives the shader stage, such as vertex or fragment, and a pointer to its source text. It asks OpenGL for a shader object. If the returned name is zero, line 111 returns zero immediately; there is no object to compile or delete. With a valid name, `glShaderSource` supplies one string and a null length pointer, meaning the string is null-terminated. Compilation is then requested.

The local `ok` starts as `GL_FALSE`, and `glGetShaderiv` asks for the compile status. If compilation fails, a zero-initialized 2048-byte log buffer receives the compiler message. `fprintf` sends the `Arrakis HUD shader` diagnostic to standard error, including a newline. The failed object is deleted before returning zero. If compilation succeeds, line 123 returns its object name to the caller, transferring responsibility for later deletion. The function reports

failure but does not throw, exit the application, or continue with an unusable shader.

Triangle, Rectangle, Outline, Card, and Bar Helpers

****Source: `arrakis_hud.h`, lines 126-147.****

`triangle` takes three two-dimensional positions and a color. It obtains the shared CPU vector by reference and appends exactly three vertices, each with the same RGBA values. These pushes preserve order. With the final `GL_TRIANGLES` draw call, each consecutive triple is one triangle. There is no index buffer and no attempt to share corner vertices between HUD shapes.

`rect` treats (x, y) as the upper-left corner and w, h as extents in the downward-y canvas. Non-positive width or height makes it return without appending anything. Otherwise it constructs the four corners and covers them using two triangles, split along the diagonal from the upper-left to the lower-right corner. The first triangle runs through top-left, top-right, and bottom-right; the second uses top-left, bottom-right, and bottom-left. Six vertices are appended, even though the mathematical rectangle has only four distinct corners.

`outline` builds a one-unit top edge at y , bottom edge at $y+h-1$, left edge at x , and right edge at $x+w-1$. This uses rectangle geometry rather than OpenGL line primitives, making thickness explicit in canvas units. The corner areas overlap, so this is not a single stroked polygon. `card` draws its dark background first, its faint outline second, and a two-unit accent strip at the left last. The default accent is edge; warning or action cards can supply a stronger color.

`bar` first draws a full-width edge background, then draws a foreground with width $w * \text{unit}(\text{amount})$. Its default height is four units, although callers often supply three or five. The amount is sanitized and bounded; no explicit condition is needed for zero because a zero-width foreground rectangle is ignored by `rect`. The order of appending determines visual layering when blending later runs. In this batching scheme, creating a card, adding its text, and later drawing an overlay naturally puts later triangles over earlier ones without multiple draw calls.

The Complete Bitmap Font

Five-Bit Rows and Every Glyph Entry

****Source: `arrakis_hud.h`, lines 149-204.****

The font is a small hand-coded bitmap font, five columns wide and seven rows high. It needs no image file or texture. `glyph(c)` returns seven unsigned bytes, but only the low five bits of each byte are meaningful. Row zero is the top row. Bit 16 is the leftmost column, followed by 8, 4, 2, and 1 toward the right. A set bit means a filled square. The comment at line 149 anticipates the optimization in the text renderer: adjacent set bits in one row will become one wider rectangle.

Here is the complete numeric vocabulary needed to decode every entry. Zero is 00000; 1 is 00001; 2 is 00010; 4 is 00100; 6 is 00110; 7 is 00111; 8 is 01000; 10 is 01010; 12 is 01100; 13 is 01101; 14 is 01110; 15 is 01111; 16 is 10000; 17 is 10001; 18 is 10010; 19 is 10011; 20 is 10100; 21 is 10101; 23 is 10111; 24 is 11000; 25 is 11001; 27 is 11011; 30 is 11110; and 31 is 11111. The row lists below therefore identify the exact shape of every supported character, not just its name.

Source Line	Character	Rows From Top to Bottom	How the Shape Is Constructed
152	A	14, 17, 17, 31, 17, 17, 17	A centered three-pixel top, two vertical sides, and a full-width middle crossbar.
153	B	30, 17, 17, 30, 17, 17, 30	A left stem with three nearly full horizontal bars and right edges between them.
154	C	14, 17, 16, 16, 16, 17, 14	Rounded top and bottom; the three middle rows retain only the left edge.

Source Line	Character	Rows From Top to Bottom	How the Shape Is Constructed
155	D	30, 17, 17, 17, 17, 17, 30	A straight left stem and a right edge, with the outer upper and lower right corners omitted.
156	E	31, 16, 16, 30, 16, 16, 31	Full top and bottom bars, a shorter middle bar, and a left stem.
157	F	31, 16, 16, 30, 16, 16, 16	The E pattern without its bottom bar.
158	G	14, 17, 16, 23, 17, 17, 15	A C-like outline with right-side interior pixels and a fuller lower-right closure.
159	H	17, 17, 17, 31, 17, 17, 17	Two vertical stems joined by a complete middle bar.
160	I	31, 4, 4, 4, 4, 4, 31	Full-width top and bottom bars with a centered vertical stem.
161	J	7, 2, 2, 2, 18, 18, 12	A top-right cap, a near-right stem, and a hook returning toward the lower left.
162	K	17, 18, 20, 24, 20, 18, 17	The left stem stays on while the second stroke approaches it and moves away diagonally.
163	L	16, 16, 16, 16, 16, 16, 31	A left stem ending in a complete bottom bar.
164	M	17, 27, 21, 21, 17, 17, 17	Two sides with a pair of inward upper diagonals and centered upper pixels.
165	N	17, 25, 21, 19, 17, 17, 17	Two sides with an upper-left to lower-right internal diagonal in the early rows.
166	O	14, 17, 17, 17, 17, 17, 14	A closed outline with trimmed corners.
167	P	30, 17, 17, 30, 16, 16, 16	A closed upper bowl over a left-only lower stem.
168	Q	14, 17, 17, 17, 21, 18, 13	An O-like bowl altered at its bottom to introduce a diagonal tail.
169	R	30, 17, 17, 30, 20, 18, 17	The P upper bowl followed by a diagonal leg to the right.
170	S	15, 16, 16, 14, 1, 1, 30	An upper right-reaching bar, left upper stroke, middle bar, right lower stroke, and lower left-reaching bar.
171	T	31, 4, 4, 4, 4, 4, 4	A full-width top and centered stem.
172	U	17, 17, 17, 17, 17, 17, 14	Two sides ending in a centered three-pixel base.
173	V	17, 17, 17, 17, 17, 10, 4	Two sides narrow to paired inner pixels and then a centered point.

Source Line	Character	Rows From Top to Bottom	How the Shape Is Constructed
174	W	17, 17, 17, 21, 21, 21, 10	Two outer strokes with a lower central stroke and a paired inner base.
175	X	17, 17, 10, 4, 10, 17, 17	Two diagonals meet at the center and diverge again.
176	Y	17, 17, 10, 4, 4, 4, 4	Diagonals merge into a centered lower stem.
177	Z	31, 1, 2, 4, 8, 16, 31	Full top and bottom joined by a descending right-to-left diagonal.
178	0	14, 17, 19, 21, 25, 17, 14	The closed O outline plus an internal diagonal distinguishing the digit.
179	1	4, 12, 4, 4, 4, 4, 14	A central stem, a small upper-left flag, and a three-pixel base.
180	2	14, 17, 1, 2, 4, 8, 31	A curved top, a diagonal down toward the left, and a full bottom bar.
181	3	30, 1, 1, 14, 1, 1, 30	Three horizontal regions joined by right-side strokes.
182	4	2, 6, 10, 18, 31, 2, 2	A diagonal into a full crossbar with a near-right stem continuing below.
183	5	31, 16, 16, 30, 1, 1, 30	A full top, left upper stroke, and rounded lower-right bowl.
184	6	14, 16, 16, 30, 17, 17, 14	A left-connected upper curve and a closed lower bowl.
185	7	31, 1, 2, 4, 8, 8, 8	A full top and diagonal into a near-left lower stem.
186	8	14, 17, 17, 14, 17, 17, 14	Two closed bowls meeting in a centered middle bar.
187	9	14, 17, 17, 15, 1, 1, 14	A closed upper bowl with a right lower stroke and curved base.
188	/	1, 1, 2, 4, 8, 16, 16	A diagonal from the upper right to the lower left.
189	+	0, 4, 4, 31, 4, 4, 0	A central vertical segment crossing a full-width middle row.
190	-	0, 0, 0, 31, 0, 0, 0	A single full-width middle row.
191	:	0, 4, 4, 0, 4, 4, 0	Two two-pixel-tall centered dots.
192	.	0, 0, 0, 0, 0, 6, 6	A two-by-two lower dot.
193	,	0, 0, 0, 0, 0, 4, 8	A small lower dot with a leftward descending tail.
194	%	25, 25, 2, 4, 8, 19, 19	Paired corner marks separated by a diagonal.

Source Line	Character	Rows From Top to Bottom	How the Shape Is Constructed
195	!	4, 4, 4, 4, 4, 0, 4	A centered stem, gap, and terminal dot.
196	?	14, 17, 1, 2, 4, 0, 4	A curved hook, descending center, gap, and dot.
197	(	2, 4, 8, 8, 8, 4, 2	A parenthesis bowing left in its middle.
198	)	8, 4, 2, 2, 2, 4, 8	The horizontally mirrored parenthesis.
199	=	0, 0, 31, 0, 31, 0, 0	Two complete horizontal bars with a blank row between.
200	_	0, 0, 0, 0, 0, 0, 31	A complete bottom row.
201	space	0, 0, 0, 0, 0, 0, 0	No visible pixels, but the text renderer still advances the cursor.
202	any unsupported character	14, 17, 1, 2, 4, 0, 4	The exact question-mark shape, making unsupported input visibly identifiable.

The switch begins at line 151, returns immediately from each case, and closes at line 203 before the function closes at 204. There is no fall-through and no need for `break` after a returned array. There are 26 uppercase letters, ten digits, 14 supported non-letter entries including space, and one default branch. Lowercase letters are handled elsewhere by conversion to uppercase. Apostrophes and square brackets have no case. Consequently the failure sentence's apostrophe in `WORM'S` and the telemetry string `[MUTED]` do not render literally: each unsupported punctuation character appears as `?`. That is actual behavior, not an extra font feature.

Text Width and Rectangle-Based Rendering

****Source: `arrakis_hud.h`, lines 205-222.****

`textWidth` returns zero for an empty string. For a nonempty string of `n` bytes, it returns $(6*n-1)*size$. Each character has five columns and a one-column gap; the final character does not need a trailing gap. The explicit floating-point conversion avoids performing the full width expression in an unsigned string-size type. Width counts all characters, including spaces and characters whose painted pixels do not touch both outer columns.

`text` walks the string as unsigned bytes. That avoids negative character values when testing ASCII ranges. A byte between `a` and `z` is shifted by subtracting `a` and adding `A`; other bytes retain their value before the cast to `char`. The resulting character selects the seven glyph rows.

The outer row loop runs from zero through six. The inner column loop deliberately has no increment expression in its header because the body advances by either one unlit position or a whole lit run. `16 >> column` creates the mask for the current left-to-right column. If bitwise AND with the row is zero, the negated test is true; the code increments the column and continues without drawing. If the bit is set, `first=column++` remembers the beginning and advances past the first lit pixel. The `while` loop then advances through consecutive set bits, stopping before column five or before an unlit bit.

One rectangle is emitted at `x+first*size, y+row*size`. Its width is the number of pixels in the run multiplied by `size`; its height is one pixel multiplied by `size`. A five-pixel horizontal font stroke therefore requires six triangle vertices, not thirty. After all seven rows, the character origin advances by `6*size`, preserving the one-column inter-character gap. The renderer is proportional only in scale, not in character width: `I`, `M`, and space all advance equally. It also has no newline interpretation; multiline behavior comes from wrapping and the separate `lines` helper.

Word Wrapping, Alignment, and Line Limits

****Source: `arrakis_hud.h`, lines 223-255.****

`wrap` estimates the maximum number of characters that fit with the same width formula used by the font. Solving $(6*n-1)*size \leq width$ gives $n \leq (width+size)/(6*size)$. Line 224 floors that value and takes at least one before converting to `std::size_t`. Actual callers supply positive font sizes; the function is not a general validation routine for zero or negative size.

The function creates an output vector, a pending line, and a pending word. The lambda `append`, capturing these by reference, is a local operation for transferring a completed word into the output. An empty word returns immediately. If a nonempty existing line plus one separating space plus the word would exceed the column count, the existing line is emitted and cleared. A word longer than the available column count is split repeatedly: each leading substring of exactly `columns` characters is emitted, then erased from the pending word. Any remainder is added to the line, with one space first only if the line already contains text. The word is cleared so it cannot be appended twice.

The byte loop treats any byte at or below ASCII space as whitespace. It first flushes the pending word. For a newline specifically, it then emits the current line, even if empty, and clears it. Ordinary spaces, tabs, and other low control bytes do not explicitly force new lines; repeated whitespace is collapsed when words are joined. A non-whitespace byte below 127 is kept, while a byte at least 127 becomes `?`. This is byte-oriented ASCII handling, not UTF-8 decoding, so a multibyte character can become multiple question marks. Unsupported printable ASCII such as an apostrophe survives wrapping but later reaches the glyph fallback.

After the loop, `append()` handles the final word, and a nonempty final line is added. The vector is returned by value. Very long exact-multiple words can leave no remainder, and an explicit newline can add an empty line after such processing; this follows from the separate splitting and newline branches. Normal HUD strings contain manageable words and use explicit newlines mainly to separate introductory instructions.

`centered` subtracts `textWidth` from the supplied region width, takes half of the difference, and offsets the text origin by that amount. It does not clip or shrink text if the difference is negative. This helper is defined but not called elsewhere in this header. `lines` takes the smaller of the content length and a maximum count, whose default is 100, then draws each selected line at $y+i*size*10$. A glyph is seven pixels high, so the ten-pixel step leaves three pixels of vertical separation at the selected scale. Limiting count drops later lines rather than rewriting their contents.

The North-Up Radar

Grid, World Mapping, and Marker Shapes

****Source: `arrakis_hud.h`, lines 257-294.****

`radar` first emits a square card. A loop with `i` equal to one, two, and three draws vertical and horizontal lines at one quarter, one half, and three quarters of side. Each grid line stays one unit inside the outer border and spans `side-2`. The result is a four-by-four reference grid, not an automatically scaled terrain map.

The local point lambda receives a position, color, and integer marker type. For each position component, it replaces non-finite input with zero, clamps to -300 through +300, adds 300, divides by 600, and scales to `side-12`. Adding `x+6` or `y+6` places the useful map inside a six-unit inset. The negative world limit lands at the inner left or top boundary; the positive limit lands at the inner right or bottom boundary. Out-of-range objects stick to the boundary instead of disappearing. The comment in line 265 emphasizes that this map stays north-up even when the heading-locked chase camera turns.

Type zero is the player triangle. Heading is sanitized and multiplied by 0.01745329252, the degrees-to-radians conversion factor. `forward=(-sin(yaw), -cos(yaw))` points up the radar at zero degrees; `right=(-forward.y, forward.x)` is its perpendicular. The triangle's tip is four units forward from the marker center, while the tail center is three units backward. The two tail corners lie four units to either side of that tail center. Passing these three points to `triangle` turns heading into an unmistakable directional arrow. The negative sine and cosine belong to this screen-map convention; they should not be replaced by a guessed three-dimensional forward vector.

Type one is an eight-by-eight outline centered on the position, used for the base. Type two is a filled six-by-six square, used for the harvester. Type four is a filled three-by-three square, used for crew. Every other type uses two triangles meeting along a vertical diagonal to produce a diamond with tips four units above, below, left, and right. The worm is explicitly passed type three and therefore gets that diamond branch.

Drawing order is base, all crew entries, harvester, worm, and player. Later markers can cover earlier ones if they coincide. Crew iteration uses const references to avoid copying each GLM vector. `pickup` has no corresponding call. Labels are optional: the `if( labels )` block emits `SECTOR / +/-300` in muted color 18 units above the map; `YOU / BASE` in cyan nine units below; and `CREW, HARV, and WORM` 26 units below in amber, white, and threat color. The last two begin 47 and 92 units to the right. These are legends, not labels individually positioned beside each object.

Title, Pause, and Results Screens

Overlay Choice and Responsive Measurements

****Source: `arrakis_hud.h`, lines 296-322.****

`over lay` begins by adding a full-canvas dark rectangle with `( 0.01, 0.018, 0.022, 0.78 )`. It darkens the already composed HUD and underlying scene. `result=s.ended` takes priority; the local `title` is true only when the mission is not ended and the input title flag is true. Otherwise the overlay is the pause design. This local precedence also resolves snapshots with more than one flag set.

The horizontal margin is 12 below width 480, otherwise 28. Panel width is the smaller of 680 and the available width after both margins. Interior padding is 14 when the panel is narrower than 420 or the canvas shorter than 420, otherwise 28. Content width subtracts that padding twice. Text pixel scale becomes one below height 300; otherwise it becomes 1.5 for a panel below width 380 or a height below 420, and two for roomier screens. Heading scale is two below height 300, 2.5 for a panel below width 420 or height below 420, and four otherwise. These choices reduce spacing and type size selectively instead of uniformly squeezing a desktop design.

The heading is exactly `MISSION CLOSED, HARVESTER FLIGHT, or FLIGHT PAUSED` according to the selected mode. For a result, the code compares the prompt with the exact string `ORNITHOPTER LOST IN THE WORM'S MAW`. A match chooses `ORNITHOPTER LOST IN THE WORM'S MAW. DELIVERED CREW REMAIN SAFE.`; otherwise it chooses `RESCUE COMPLETE. ONLY CREW DELIVERED TO BASE COUNT. EVERY LIFE COUNTS..` This is a display-message test, not collision detection. The apostrophe survives the string comparison correctly even though its font glyph is unsupported.

For the title mode, four explicit instruction lines state `FLEEING HARVESTER RELEASES 1-4 CREW AT A TIME., AMBER GROUPS WAIT ON SAND. 8 RESCUE SEATS., MOUSE STEERS. FLY LOW. HOLD SPACE TO WINCH., and RETURN TO CYAN BASE. HOLD SPACE TO BANK RESCUED..` Adjacent C++ string literals concatenate into one string containing the specified newline separators. Pause mode uses `THE RESCUE IS ON HOLD. YOUR CREW IS COUNTING ON YOU..` All three possibilities pass through `wrap`, so long lines still break at the current content width.

The key instruction is independently wrapped: `ENTER NEXT MISSION / R RETRY, ENTER START, or P RESUME`. `lineH=size*10` matches the `lines` helper. Results reserve `lineH*3+12` for their three statistical rows and a gap; other modes reserve zero. Panel height adds twice the inset, 23 for the branding step, seven heading pixels at heading scale, 18 after the heading, the result reserve, all wrapped body and key lines at `lineH`, and 25 for the final separator spacing. Horizontal position centers the panel. Vertical position centers it unless that would be less than eight, in which case the top is eight. The card accent is amber for results and cyan otherwise.

These calculations are responsive but not an absolute overflow guarantee. If a framebuffer is extremely tiny or unusually short, the computed panel can extend below it. There is no final panel-height clamp, scroll area, or scissor-based text clipping in this function. It prioritizes readable sizes and lets framebuffer bounds provide the ultimate clipping.

Overlay Content and Cursor Advancement

****Source: `arrakis_hud.h`, lines 323-341.****

The mutable cursor begins at the panel's top inset. The header `ARRAKIS / SEARCH + RESCUE` is drawn in muted color at scale 1.5, after which the cursor advances 23. The selected heading is then drawn in bone color at `headingSize`, and the cursor advances its seven-row glyph height plus 18.

For results only, the first line reads `SECURED <rescued> / <total>` in cyan. The second reads `BEST <max(best, rescued)> / MISSION <wave>` in bone. Taking the maximum means a just-achieved score is visible as the best even if the caller has not yet synchronized its stored record. The third reads `ABOARD <aboard> / LOST <lost>` in muted color. Each count passes through the nonnegative number helper. Cursor increments match `lineH` between rows, then add 12 after the final row.

The wrapped body is drawn in muted color, and the cursor advances by its entire line count times `lineH` plus 12. A one-unit horizontal separator spans `contentW`. Another advance of 13 puts the key instructions below it; these are cyan. This cursor scheme accounts for all the components used in the panel-height expression. The function closes after adding geometry; no rendering or input handling happens inside it.

Composing the In-Game HUD

Global Layout Decisions and the Countdown

****Source: `arrakis_hud.h`, lines 343-355.****

`compose(w, h, s)` is the central geometry builder. Its `w, h` are layout-canvas dimensions, not necessarily raw framebuffer dimensions. Margin `m` is ten when width is below 600 or height below 400, otherwise 22. `inner=w-2*m` is the content width between margins. `compact` is true below width 760 or height 440. `shortView` is true below height 360. These are independent tests: a wide but short screen still enters compact mode.

`extraction` checks `attackTime>=0`. It selects `extractionRemaining` instead of ordinary `remaining`, and a fixed duration of 60 instead of `missionDuration`. Before extraction, the duration is sanitized with a fallback of 210 and constrained to at least 0.001, preventing division by zero in the time bar. A non-finite remaining value is treated as zero in the danger test. Danger is true when remaining time is at most 15 or when extraction is active. Thus the entire extraction phase uses warning styling, not only its last fifteen seconds.

The label precedence is `EXTRACTION WINDOW` for extraction, then `BREACH IMMINENT` for low pre-breach time, otherwise `TIME TO BREACH`. Danger uses amber; ordinary time uses bone. The top card height is 78 for compact short view, 112 for other compact views, and 106 for noncompact views. The initial card spans the full inner width. Label choice, clock formatting, and bar clamping are separate: even inconsistent caller data does not make the displayed fraction overfill the bar.

Full-Width Desktop Header

****Source: `arrakis_hud.h`, lines 356-375.****

The noncompact branch arranges the top card as branding, crew status, and a timer. Branding begins 18 units from the left and 16 from the top with `ARRAKIS` at scale three. `FLEEING HARVESTER` appears at top offset 47, scale 1.5, muted. `SEARCH + RESCUE / <wave>` appears at offset 76, scale 1.5, cyan. The positions are fixed relative to the panel, not inferred from text height.

`scoreX=m+inner*0.30` starts the central status cluster at thirty percent of the inner width. `SECURED <rescued>/<total>` is cyan at scale 2.5 and y offset 15. `ABOARD <aboard>/8` appears at offset 44; `INSIDE <inside>` shares that row 126 units to the right in muted color. A loop draws eight seat slots at x spacing 14, each ten units wide and five high, at y offset 64. Slot `i` is cyan when `i<s.aboard`, otherwise edge. The comparison uses the original count; a negative count fills none and a count above eight fills all, but the code never creates more than eight slots.

`GROUPS <releasedGroups>` is amber, positioned 126 units to the right of `scoreX` on the seat row. `SAND <waiting> / LOST <lost>` is muted at y offset 82. `SAND` follows the documented Running-plus-Waiting outside count rather than the inside count.

`timerX=m+inner-230` anchors the timer cluster near the right. The label is at y offset 15, the clock at 39 and scale three, and a 210-by-five time bar at 74. Its amount is sanitized remaining time divided by the selected duration. At y offset 87, `SECURE CREW AT CYAN BASE` reminds the player that boarding alone is not scoring. The branch ends at line 375 before the alternate compact branch.

Compact and Very Short Headers

****Source: `arrakis_hud.h`, lines 375-392.****

The compact branch uses a combined `ARRAKIS / FLEEING HARVESTER` title at x offset 12 and y offset ten. Its scale is 1.5 when the inner width is below 330, otherwise two. `row` is y offset 26 for short views, 32 otherwise. The timer label sits on that row; the clock is two units higher and right-aligned using its measured width and a twelve-unit inset.

The timer bar is only 74 units wide and three high, ending at that same right inset. Its y offset is 56 for short views but 48 for other compact views. This intentional rearrangement puts it below the seat row when space is especially short. `statsY` is offset 43 for short views and 54 otherwise. At that position, `SAVED <rescued>/<total>` is cyan on the left and `SEATS <aboard>/8` is right-aligned on the right. The change from `SECURED` to `SAVED` shortens the label; it does not change which numeric field is displayed.

The next left-aligned line combines `SAND <waiting> INSIDE <inside> GROUPS <releasedGroups>`, at offset 61 in short view or 76 otherwise. If the view is not short, an extra line at offset 96 shows `LOST <lost> / WAVE <wave>`. Only in that non-short branch, and only if inner width is at least 360, does the code draw a compact eight-seat diagram. Each slot is eight by four, separated by twelve units, beginning 104 units from the right and sitting at offset 99. These omissions reduce clutter without changing any mission values.

Wrapped Controls and the Action Card

****Source: `arrakis_hud.h`, lines 394-422.****

The comment in lines 394-395 explains the design principle: controls wrap at readable pixel sizes instead of shrinking an entire 1280-pixel design. The control font scale is always 1.5. The complete instruction string is `MOUSE STEER / W S THRUST / A D STRAFE / Q E ALT / SPACE WINCH / SHIFT BOOST / C CAMERA / M MUTE / P PAUSE / R RETRY`. It identifies mouse steering, forward/back thrust, lateral strafe, altitude controls, winching, boosting, camera choice, mute, pause, and retry. The HUD merely displays those mappings; actual key handling belongs to the game.

Wrapping uses `inner-20`, allowing ten units on both sides. Controls-card height is fifteen units per wrapped line plus 14. `controlsY=h-m-controlsH` anchors its bottom above the bottom margin. The card spans the inner width, and text starts ten units from its left and eight from its top. A narrow screen makes more lines and a taller bottom card, rather than smaller letters.

The action message initially copies `s.prompt`. An empty prompt chooses one of three defaults in descending priority: with at least eight aboard, `SEATS FULL / RETURN TO CYAN BASE`; with a positive smaller aboard count, `RETURN TO BASE / HOLD SPACE TO BANK CREW`; otherwise `FLY LOW TO CREW / HOLD SPACE TO WINCH`. Active unloading overrides either a prompt or a default with `BANKING CREW / HOLD SPACE`. Only when unloading is not positive does positive pickup progress override with `WINCH ACTIVE / HOLD SPACE`. The `if` followed by `else if` gives unloading explicit precedence if both progress values are positive.

`sideRadar` requires all three conditions: short view, inner width at least 280, and enough room that a 64-unit radar beginning at `controlsY-72` is at least six units below the top card. If true, action width reserves 76 units for that radar; otherwise it uses the full inner width. In either case width is capped at 620. Action text scale is 1.5 for compact mode and two for desktop mode. The message wraps within `actionW-28`, reserving fourteen-unit side insets.

If wrapping produces more than two lines, the vector is resized to two. When the retained last line contains at least three characters, its final three characters are replaced by `...`. This communicates truncation without adding width. A shorter retained line receives no ellipsis. Action height is its retained line count times the line step plus 23. Its bottom sits eight units above the controls card. With a side radar, it is right-aligned to the margin; otherwise it is centered across the whole canvas.

The card gets a cyan accent, and its text begins at x inset 14 and y inset ten. The progress selection uses unloading if it is positive, otherwise pickup. The bar is three units high, fourteen units inset from both sides, and nine units above the card's bottom. Its unit sanitization handles out-of-range values. The message-selection conditions themselves do not call `finite`; for example, a NaN progress fails the positive comparison, while a positive infinity selects the active message but produces a zero displayed bar through `unit`. This is the precise split between display formatting and raw conditional state.

Radar Placement, Telemetry, and Room-Dependent Omission

****Source: `arrakis_hud.h`, lines 424-442.****

The normal radar begins below the top card by ten units in compact mode or 32 on desktop. `available` measures space from that radar top to the action card, subtracting six units in compact mode or 52 on desktop. The larger desktop reserve accommodates legends and breathing room. Requested side length is capped at 92 for compact mode and 156 otherwise, but cannot exceed the available vertical space.

If `sideRadar` is true, the special radar is drawn at the left margin, 72 units above the controls top, with side 64 and no labels. Otherwise, a normal radar is drawn only when the computed side is at least 40, at the right margin. Labels are enabled only for a noncompact radar at least 128 units wide. The `else if` means the two radar placements never both execute.

Telemetry appears only when there is no side radar, at least 88 units of vertical room, and either the view is noncompact or inner width is at least 420. Its width is 184 in compact mode and 222 otherwise. `pursuitRoom` checks available height at least 112 and chooses a 112-unit card instead of an 88-unit card. This gate prevents a pursuit row from being added when only the basic telemetry fits.

The first row is ALT <rounded altitude> M at y offset twelve. The second is SPD <rounded speed> / FPS <rounded fps>, at offset 31. When muted, it appends [MUTED] and uses amber rather than muted color. The square brackets fall back to question-mark glyphs, as described in the font section. BOOST appears at offset 52; its five-high cyan bar begins x offset 72 and y offset 55 and spans `tw-86`, leaving a right inset of fourteen.

WORM RANGE <rounded distance> M appears at offset 72 in amber. Its distance is made finite and clamped to a minimum of zero before passing through `decimal`, unlike altitude and speed, which may legitimately format negative values. If pursuit room exists, PURSUIT appears at offset 92 in amber and a five-high threat-colored bar begins x offset 86 and y offset 95, with width `tw-100`. Both normalized bars use the generic bar helper and therefore bound their foreground to the background.

Flight Guides and Overlay Order

****Source: `arrakis_hud.h`, lines 443-452.****

Guides are emitted only when the mission is not ended, not on the title screen, and not paused. A local copy of cyan has alpha reduced to 0.35. Nested range loops choose dx and dy from -1 and +1, producing all four combinations. Guide centers lie at 44 or 56 percent of canvas width and height: `0.5+sign*0.06`.

At each position, one seven-by-one rectangle and one one-by-seven rectangle create an L-shaped corner. Positive dx subtracts seven from the horizontal bar's starting x, so it extends inward toward the screen center; negative dx does not. Positive dy similarly subtracts seven from the vertical bar's y. Thus the four marks outline a quiet central aiming or flight region rather than drawing a full crosshair over the scene.

Finally, if any of ended, title, or paused is true, `overlay` is called. Because it is called after all other composition, its dimmer and panel triangles are appended last and cover the normal interface. The underlying HUD is still composed rather than omitted; the overlay darkens it. Closing line 452 ends `compose`, and line 454 ends the internal namespace.

HUD Initialization, Drawing, and Cleanup

Shader Sources and Program Linking

****Source: `arrakis_hud.h`, lines 456-491.****

`initRescueHud` introduces a short namespace alias `hud`, retrieves the shared resources, and immediately returns if the program already exists. This makes normal repeated initialization calls cheap. It also means the `program` field is the initialization sentinel; the function assumes a nonzero existing program belongs to a valid resource set in the current owning context.

The vertex shader consists of adjacent C++ string literals with explicit newline escapes and requests GLSL `#version 330 core`. Attribute `location zero` is a two-component position; `location one` is a four-component color. `canvas` is a two-component uniform and `tint` is a four-component output. The main function assigns the input color to `tint` and converts pixel-style layout coordinates to clip coordinates.

For `x`, `position.x/canvas.x*2-1` maps zero to -1 and the right edge to +1. For `y`, `1-position.y/canvas.y*2` maps the top to +1 and the bottom to -1, reversing the down-growing canvas convention into OpenGL's up-growing clip convention. The resulting `z` is zero and `w` is one. Because no perspective division changes this `w`, the HUD is a flat overlay. The fragment shader receives interpolated `tint` and writes it directly to its output fragment; it does not sample a texture, apply lighting, or discard pixels.

The helper compiles both stages. If either is zero, the `if` in lines 473-477 deletes whichever stage did succeed and returns. Compiling both before checking means a fragment stage can exist even when the vertex stage failed, and this branch handles that case. Program creation has its own zero check; failure deletes both compiled shader objects and returns.

With a program, the code attaches both stages, links, and deletes the stage objects. OpenGL retains what the linked program needs; the application no longer needs the temporary shader handles. The link-status query starts from false. Failure obtains a bounded 2048-byte program log, prints it with the `Arrakis HUD Link:` prefix, deletes the unsuccessful program, and returns. No failed program is installed in `Resources`.

Vertex Array Setup and Binding Preservation

****Source: `arrakis_hud.h`, lines 492-510.****

Before configuring vertex storage, the function queries the old VAO and array-buffer bindings. It generates one HUD VAO and one VBO. If either name is zero, it deletes any object successfully generated, resets both fields to zero, deletes the otherwise linked program, and returns. Since this failure occurs before the new objects are bound, there are no new binding changes to undo in that branch.

After successful object creation, `r.program` receives the linked program and `r.canvas` receives the location of its canvas uniform. The VAO and VBO are bound. Both attributes are enabled. Location zero reads two `GL_FLOAT` values starting at byte offset zero, with no normalization and stride `sizeof(hud::Vertex)`. Location one reads four floats starting at `offsetof(hud::Vertex, r)`, the red field, with the same stride. The cast to a pointer type supplies a buffer byte offset to OpenGL; it is not dereferencing an arbitrary CPU pointer.

The old VAO and array-buffer bindings are restored explicitly. Initialization has not called `glUseProgram`, so it does not need to restore an active program. Finally, the CPU vector reserves room for 65536 vertices. `reserve` changes capacity without adding elements; the first composed frame still begins from an empty vector. It is a starting allocation, not a maximum geometry limit. No GPU vertex storage is allocated here; the drawing function manages that dynamically.

Frame Composition, Render State, Buffer Orphaning, and Draw Call

****Source: `arrakis_hud.h`, lines 512-540.****

`drawRescueHud` first returns for nonpositive framebuffer width or height. This avoids division by zero and is appropriate for a minimized or otherwise undrawable framebuffer. It calls initialization, retrieves resources, and returns if initialization left no program. Only then does it construct `GLState saved`, making restoration automatic for the subsequent draw operations.

The scale is the greater of one and the smaller of `width/1280` and `height/720`. This chooses the limiting dimension for proportional enlargement but forbids scaling below one. A 640-by-360 framebuffer therefore uses a 640-by-360 layout canvas rather than a shrunken 1280-by-720 one. A 2560-by-1440 framebuffer uses scale two and a 1280-by-720

canvas; one canvas unit then covers two framebuffer pixels. An unusually wide screen with only 720 pixels of height stays scale one because height is limiting. $w = \text{width}/\text{scale}$ and $h = \text{height}/\text{scale}$ define the dimensions passed to layout and to the vertex shader.

The vertex vector is cleared without normally releasing its capacity, then `compose` appends the entire frame. All ten capabilities named by the saved guard are disabled. Blend is then reenabled, with both equations set to addition. RGB factors are source alpha and one minus source alpha, giving the familiar translucent overlay. Alpha factors are one and one minus source alpha, so output alpha accumulates as source alpha plus destination alpha times its remaining fraction. This separate alpha setup is not identical to using source alpha for both RGB and alpha.

All color channels are made writable, polygon mode is forced to filled triangles, and the viewport is the entire framebuffer starting at zero. Disabling depth test prevents the HUD from being hidden by scene depth. Disabling the other named capabilities prevents leftover scissor, stencil, wireframe, discard, and similar settings from corrupting the overlay. The function does not clear color or depth buffers. The caller's framebuffer remains bound, and its existing image becomes the background for blending.

The HUD program is selected and its canvas uniform receives layout width and height. Its VAO and VBO are bound. `bytes` is the vector length multiplied by the actual vertex structure size. If bytes exceed GPU capacity, capacity becomes the greater of the required byte size and twice the old capacity. First use therefore grows from zero to at least the required amount; later growth tends to be geometric, reducing repeated reallocations. If the frame uses fewer bytes, capacity is retained.

`glBufferData` is called every frame with that retained capacity, a null source pointer, and `GL_DYNAMIC_DRAW`. The null pointer requests new storage without copying old data. This is called orphaning: the driver can let a previous draw finish reading the old storage while providing new storage for the current frame. It is a performance technique, not a guarantee that every driver will avoid every stall. `glBufferSubData` then copies exactly `bytes` from the CPU vector to offset zero of the new storage.

`glDrawArrays` uses `GL_TRIANGLES`, starts at vertex zero, and consumes the whole vector after conversion to `GLsizei`. All card, glyph, radar, and overlay triangles are rendered in this one call. When the function closes at line 540, `saved` is destroyed and restores the previously described state. CPU vertices remain in the shared vector until next frame's clear or final cleanup; there is no per-shape OpenGL call hidden in the geometry helpers.

Explicit Cleanup and End of Header

****Source: `arrakis_hud.h`, lines 542-552.****

`cleanupRescueHud` retrieves resources and conditionally deletes the VBO, VAO, and shader program, in that order. Each zero check avoids treating an uncreated resource as a live one. The chained assignment resets all three object fields to zero. The uniform location returns to -1 and the GPU byte capacity to zero. Swapping the CPU vector with a freshly constructed empty vector releases its allocation, unlike `clear`, which normally retains capacity.

After cleanup, a future valid call can initialize a fresh HUD because the program sentinel is zero. Cleanup should run while the owning OpenGL context is current and before that context is destroyed. It does not use a state-restoration guard; deleting an object that is currently bound has OpenGL-defined effects on bindings, so this is a lifecycle operation rather than a promised transparent render operation. Line 550 closes cleanup, and line 552 closes the include guard begun at lines 1-2.

The Sandworm's Procedural Geometry

The remaining sections explain `arrakis_worm.h` completely. Unlike the HUD, the worm uses the scene's existing mesh upload and material drawing helpers. It has a changing body mesh, separately constructed mouth surfaces, many individual curved teeth combined into one mesh, and an animation pose shared between scene render passes.

Header Guard, Dependencies, Constants, and Cache Fields

****Source: `arrakis_worm.h`, lines 1-20 and 258.****

Lines 1-2 begin the `ARRAKIS_WORM_H` include guard, closed at line 360. The comments in lines 4-5 describe integration: include the header after the rock-formation drawing definitions and before `drawFullScene`, initialize and clean up while the GL context is current, and draw in both scene passes. This header is not independently self-contained. It includes `<cmath>` and `<vector>` in lines 6-7, but expects GLM, OpenGL declarations, scene vertex and mesh types, materials, terrain height queries, upload routines, drawing helpers, and the shared sphere mesh to have been declared already by the including translation unit.

In the surrounding renderer, `Vertex` contains `pos`, `normal`, and `uv`: a three-dimensional position, a three-dimensional lighting normal, and two texture coordinates. `Mesh` contains `VAO`, `VBO`, `EBO`, index count, and draw mode. The `VAO` describes vertex attributes; the `VBO` contains vertex data; the `EBO` contains the unsigned indices selecting vertices for triangles. `uploadMesh` creates these GPU objects and returns a `Mesh`. `drawMeshPrimitive` supplies the current pass's uniforms and draws the indexed mesh. A `Material` has diffuse and specular colors, shininess, emissive color, and an `isSand` flag. The worm uses these existing types instead of defining replacements.

Line 9 opens `arrakis_worm_detail`, and line 258 closes it. `pi` at line 11 is the single-precision constant 3.14159265358979323846, used in all angular construction. `bodyRows=192` means 192 longitudinal intervals, not 192 total vertex rings. `bodySlices=96` means 96 angular intervals around each ring, not 96 stored vertices per ring. Both axes need an extra endpoint, so the full body grid has 193 rings of 97 vertices each.

Line 14 declares five static `Mesh` objects. `body` is the flexible skin; `lip` is the thick exterior rim; `funnel` is the narrowing visible mouth interior; `throat` is the deep dark continuation and recessed closure; `teeth` is the aggregate tooth geometry. `bodyVertices` at line 15 is the CPU copy retained for deformation and uploading. Other geometry is built once and does not require a persistent CPU vector here.

`ready`, initially false, indicates whether initialization has been performed. It is not an OpenGL error-status query. `poseValid`, also false, says whether the remembered input tuple corresponds to the currently uploaded body pose. `lastCenter` starts at the zero vector. `lastAttack` and `lastTime` start at zero; `lastHeading` and `lastProgress` also start at zero. Those values are meaningful as a cache only after `poseValid` becomes true. A deliberately separate validity flag avoids guessing that a zero-valued input tuple must mean an upload has already happened.

The static namespace variables have internal linkage, so separate translation units including this header would have separate data instances. The actual project includes this implementation into its scene translation unit rather than treating it as a general multi-context library. No cache member contains a shader, framebuffer, or separate shadow pose.

Smooth Transitions and Mesh Destruction

****Source: `arrakis_worm.h`, lines 22-32.****

`smooth(a, b, t)` converts a quantity into a smooth progress value across the interval from `a` to `b`. It first computes $(t-a)/(b-a)$ and clamps it to zero through one. It then returns $u*u*(3-2*u)$, the cubic smoothstep polynomial. The polynomial is zero at `u` zero, one at `u` one, and has zero first derivative at both ends. This makes staged rises, lunges, retreats, and tapers start and stop gently rather than introducing abrupt velocity changes.

The helper assumes distinct interval endpoints. It has no branch for `a==b`, so such a call would divide by zero. Every interval used in this header has distinct endpoints. It also does not itself screen out non-finite `t`; the public drawing function checks its animation inputs before calling the pose logic.

`destroy(mesh)` conditionally deletes the `EBO`, `VBO`, and `VAO`, in that order. Each test checks the object name, allowing cleanup of a default or partially populated mesh without issuing an intentional delete for an absent resource. `mesh=Mesh{}` then resets not only the three handles but also its index count and default draw mode according to the scene's `Mesh` member initializers. This is a complete logical reset of the record, not merely the deletion of GPU storage. As with all OpenGL deletion, the correct current context is required.

Shared Surface Construction

Rectangular Grid Indices and Triangle Winding

****Source: arrakis_worm.h, lines 34-43.****

`gridIndices(indices, rows, slices)` builds triangle connectivity for a rectangular grid whose stored ring width is `slices+1`. It reserves `rows*slices*6` index slots. There are `rows*slices` cells, each split into two triangles, each triangle containing three indices. `reserve` preallocates capacity without inserting values. This routine appends rather than clearing its argument; its callers pass newly created empty vectors.

The `j` loop visits row intervals zero through `rows-1`. The nested `i` loop visits angular intervals zero through `slices-1`. `a=j*(slices+1)+i` locates the current cell's first corner. `b=a+1` is the next vertex around the same ring. `c=a+slices+1` is the corresponding vertex in the next ring. `d=c+1` is the next-ring next-angle corner. The inserted sequence `a, c, d, a, d, b` creates two triangles sharing the `a-to-d` diagonal.

This consistent winding controls which side of each surface is considered the front and the sign of cross-product normals. The formula uses every adjacent pair of stored angles, including the final pair ending at the duplicated seam vertex. It does not wrap the index modulo `slices`, because the extra vertex explicitly represents the angular endpoint. The same connectivity supports both a straight revolved profile and the much more complicated bent body, provided their vertices use this ring-major layout.

For the body, 192 by 96 produces 18432 cells, 36864 triangles, and 110592 indices. These connectivity numbers never change during animation. Deformation changes positions and normals, not the number or order of triangles. The closing braces in lines 41-43 finish the inner loop, outer loop, and function respectively.

Triangle-Derived Surface Normals and the Duplicated Seam

****Source: arrakis_worm.h, lines 45-61.****

`surfaceNormals` begins by setting every vertex normal to zero. It then visits the index vector in steps of three, matching the triangle groups created by `gridIndices`. References `a`, `b`, and `c` select the actual vertex records for those indices. The vector `cross(b.pos-a.pos, c.pos-a.pos)` is perpendicular to the triangle and has length proportional to twice its area. Its direction depends on the index winding. The same unnormalized vector is added to the normal accumulator at all three corners.

Because the face vector is not normalized before accumulation, larger triangles contribute more strongly than smaller ones. This is area-weighted averaging. When the accumulators are eventually normalized, neighboring faces produce smooth vertex lighting rather than isolated flat face normals. It is useful for the gently roughened mouth surfaces.

The UV seam has two stored vertices at the same nominal angular position: the first angle is zero and the last angle is one full turn. Their separate UV values permit a continuous parameter interval from zero to one, but separate accumulation would otherwise give each side only its own adjoining faces. The `j` loop at line 56 advances by `slices+1`, jumping to the beginning of each ring. It adds the first and final vertex's accumulated normals and assigns that sum to both. This welds their shading, not their indices or positions.

The comment in line 55 specifies why this should not be used indiscriminately on tooth surfaces: teeth are separate objects, and averaging unrelated surfaces together would blur their lighting. In fact, the tooth builder supplies its own normals and does not call this function. A final range loop normalizes every accumulated vector to unit length. There is no zero-length fallback here; callers are expected to supply usable nondegenerate surfaces. The later throat floor is added after this computation specifically to give it independent upward normals.

Revolving a Profile Into a Lathe Surface

****Source: arrakis_worm.h, lines 63-84.****

The comments in lines 63-64 explain the geometric ordering: the profile follows the exterior upward toward the lip, then proceeds down the inner funnel. With the same triangle winding, an increasing-height exterior has normals pointing away from the axis, while a descending interior has normals pointing into the mouth cavity. The normal direction comes

from traversal direction and the cross product, not from a separate branch that labels a surface as inside or outside.

`lathe(profile, roughness, deepFloor)` receives radius-height points in `glm::vec2` records. The x component is radius and the y component is vertical position in the local mouth coordinate system. Revolving those points around the y axis creates a surface of revolution, analogous to shaping clay on a spinning wheel. `deepFloor` defaults to false. Each lathe uses 160 angular slices, a higher angular resolution than the body's 96 slices.

The function allocates local vertex and index vectors and reserves `profile.size()*161` vertices. It assumes a profile with at least two points; both the interpolation denominator `profile.size()-1` and the longitudinal cell count depend on that. The supplied lip, funnel, and throat profiles satisfy the assumption. The outer loop visits every profile point; the inner loop visits angles `i` zero through 160 inclusive, creating the duplicate angular seam.

`u=float(i)/slices` is normalized angular position. `a=2*pi*u` maps it to one complete revolution. The roughness formula multiplies three things: the supplied roughness amplitude, a longitudinal sine envelope, and a weighted angular wave sum. The envelope `sin(pi*j/(profile.size()-1))` is nominally zero at each end of the profile and positive in the middle, so neighboring surfaces retain their intended radius at attachment rings while interior rings gain irregularity. Floating-point trigonometry can leave tiny endpoint residuals rather than mathematically exact zero.

The angular wave sum is `0.55*sin(11*a+0.7*j) + 0.30*sin(23*a-0.9*j) + 0.15*sin(47*a+1.1*j)`. Eleven, 23, and 47 are distinct integer frequencies around a full turn. Their weights total one, and their `j`-dependent phases prevent identical bumps in every profile row. The signs and phase rates vary the directions in which the patterns shift. For amplitude 0.16, the magnitude is bounded by approximately 0.16 before the envelope; for 0.08, by approximately 0.08. This is deterministic procedural roughness, not random noise that changes every frame.

`r=profile[j].x+rough` perturbs radius only. Each vertex position is `(r*cos(a), profile[j].y, r*sin(a))`; its initial normal is zero; its UV is `(u, j/(profile.size()-1))`. The UV's first coordinate tracks the revolution and the second tracks profile row fraction, not physical arclength. After building all rings, `gridIndices` connects `profile.size()-1` longitudinal intervals, and `surfaceNormals` computes normals including the actual roughened shape.

The Recessed Floor, Its Extra Vertices, and Upload

****Source: `arrakis_worm.h`, lines 85-97.****

The optional `deepFloor` block closes only the deepest throat, not the large mouth opening. It records the current vertex count as the center index and appends a center at x and z zero and the final profile point's y. That center has normal `(0, 1, 0)` and UV `(0.5, 0.5)`.

The angular loop again includes zero through 160. Each iteration copies a vertex from the final lathe ring, overrides its normal to point upward, and appends the copy. Copying rather than reusing the existing ring preserves a hard normal transition between the narrowing throat wall and its floor. The copied UV remains the wall-ring UV; this is not a fully remapped radial disk texture layout. Here the material is mainly dark color, so geometric closure is its main purpose.

For `i` below 160, the code inserts a triangle from the center to the next copied ring vertex and then the current copied ring vertex. The indices use `center+i+2` and `center+i+1` because the center itself occupies the first newly appended slot. At the time some indices are inserted, the next ring copy will be appended in a later iteration; this is valid because all referenced vertices exist before final upload. The final `i` equals 160 adds the duplicate endpoint but no extra triangle. This makes exactly 160 floor triangles with upward winding.

The function returns `uploadMesh(v, indices)`. That creates GPU buffers while the temporary vectors still exist; they can be destroyed after their data has been uploaded. There is no stored CPU copy of these lathe vertices in the worm namespace. Both the false-floor path and true-floor path converge on the same upload return.

The Thousand Curved Teeth

Row Counts, Radii, Depths, and Deterministic Variation

****Source: `arrakis_worm.h`, lines 99-120.****

makeTeeth constructs all teeth in one mesh. There are six concentric rows, five cross-section sides per tooth, and six sampled cross-section rings along each tooth. The row counts are 192, 184, 176, 168, 152, and 128, totaling exactly 1000 teeth. The attachment radii are 13.1, 11.3, 9.4, 7.7, 6.0, and 4.5. The corresponding depths are -0.8, -2.6, -4.5, -6.3, -8.2, and -10.1. These pairs match explicit points in the funnel profile, so each row starts on an appropriate narrowing section of the inner mouth.

The vertex reserve is $1000 * (\text{steps} * \text{sides} + 1)$: 30 ring vertices and one apex per tooth, giving 31000 vertices. The index reserve is $1000 * ((\text{steps} - 1) * \text{sides} * 6 + \text{sides} * 3)$: five bridges of five quadrilateral sides, each split into two triangles, plus five final triangles at the apex. This is 165 indices per tooth and 165000 indices overall. Reserving the exact expected quantities avoids repeated vector growth during construction.

The outer loop selects a row and the inner loop visits each tooth number below that row's count.

`seed=float(tooth*17+row*131)` produces a deterministic number from its identifiers.

`variation=0.5+0.5*sin(seed*1.713)` maps a sine into zero through one. There is no random-number engine, random seed file, or per-frame regeneration: the same row and tooth produce the same result each time meshes are initialized.

The tooth angle is $2 * \pi * (\text{tooth} + 0.37 * \text{row} + 0.18 * \sin(\text{seed})) / \text{counts}[\text{row}]$. The tooth number spaces teeth around the row. The 0.37-row term offsets consecutive rows so their teeth do not form perfectly aligned radial columns. The final sine term supplies a small angular jitter measured in fractions of nominal tooth spacing.

`radial=(cos(a), 0, sin(a))` points out from the axis toward the attachment. `sideways=(-sin(a), 0, cos(a))` is a perpendicular horizontal direction that allows a tooth to curl sideways independently of inward reach.

`reach=(radii[row]-1.8)*(0.55+0.17*variation)` sets inward extent. The multiplier ranges from 0.55 to 0.72; subtracting 1.8 preserves a central region instead of forcing every tip to the axis. The possible reach ranges by row are 6.215-8.136, 5.225-6.840, 4.180-5.472, 3.245-4.248, 2.310-3.024, and 1.485-1.944. As the mouth narrows, the deeper teeth become shorter in horizontal reach.

`drop=2.1+1.1*variation` ranges from 2.1 to 3.2 downward units. `curl=0.20+0.30*sin(seed*0.91)` ranges from -0.10 to +0.50, so some teeth bend slightly the opposite way but most have a positive-side tendency.

`width=(0.075+0.035*variation)*(1-0.06*row)` sets the starting cross-section radius. Its base range is 0.075-0.110, multiplied by 1.00, 0.94, 0.88, 0.82, 0.76, and 0.70 as rows deepen. The local variable base remembers where this tooth's vertices begin in the shared vector, ensuring later indices refer to this tooth rather than a previous one.

Curved Centerline and a Moving Cross-Section Frame

****Source: arrakis_worm.h, lines 121-137.****

The k loop samples six rings with $t=k/\text{steps}$. Since k runs zero through five and the denominator is six, the sampled values are 0, 1/6, 2/6, 3/6, 4/6, and 5/6. The endpoint at one is deliberately not a small ring; it will be a single pointed apex later.

The centerline position p combines three independent directions. Its radial component is `radii[row]-reach*t`, which moves inward linearly. Its sideways component is `curl*t*t`, which starts with zero lateral slope and increasingly bends to one side. Its vertical component is `depths[row]+0.65*sin(pi*t)-drop*t*t`. The sine briefly lifts the tooth above a purely downward parabola, while the quadratic term bends it down toward the final tip. At t zero the center is exactly at its attachment radius and depth. At t one the sine is zero, the inward displacement is reach, sideways displacement is curl, and vertical displacement is negative drop.

The tangent formula is the derivative of this centerline with respect to t, normalized to unit length. The radial derivative is `-reach*radial`; the sideways derivative is $2 * \text{curl} * t * \text{sideways}$; and the vertical derivative is $0.65 * \pi * \cos(\pi * t) - 2 * \text{drop} * t$. This makes the local cross-section track the changing tooth direction rather than remaining parallel to a fixed plane.

The vector b is the normalized cross product of tangent with sideways. It is perpendicular to the tangent. The vector n is `cross(b, tangent)`, completing a perpendicular pair for the cross-section. Here n is a local frame direction, not yet a particular vertex normal. Because the inward radial derivative is nonzero for all supplied rows, the tangent does not

collapse into the sideways direction and this construction has a usable frame for the generated teeth.

Cross-section radius is $\text{width} * \text{pow}(1 - t, 0.85)$. At the attachment it is width, and it decreases toward zero. The exponent 0.85 controls how the narrowing develops along the shaft; it is not a linear cone. The five-side loop chooses angles $2 * \pi * s / \text{sides}$, then creates a normal direction $n * \cos(\text{angle}) + b * \sin(\text{angle})$. Multiplying that direction by the radius and adding p gives the surface vertex. The same direction is stored as its lighting normal. UV is $(s / \text{sides}, t)$.

Only five angular vertices are stored per ring, so there is no sixth duplicated seam vertex. Connectivity later wraps the fifth side back to the first with modulo. The supplied normals are moving-frame radial normals, an efficient approximation for a tapered curved tooth; they do not include a derivative correction for every taper slope in the way the flexible body's finite-difference normals do. The UV seam is also a wrapped five-vertex polygon rather than the explicitly duplicated zero/one seam of the lathe.

Shaft Triangles and One True Apex

****Source: arrakis_worm.h, lines 138-160.****

The next nested loops connect adjacent sampled rings. k ranges zero through four, covering five bridges; s ranges zero through four, covering the five pentagonal sides. $a0 = \text{base} + k * \text{sides} + s$ is the current corner, while $b0 = \text{base} + k * \text{sides} + (s + 1) \% \text{sides}$ is the next corner around the ring. Modulo returns to side zero after side four. Adding sides selects corresponding corners in the next ring. The six inserted indices form two triangles covering the side quadrilateral.

The comment at line 145 emphasizes the apex design. tip is the next vertex index. tipPos evaluates the same centerline at t one: radial radius becomes $\text{radii}[\text{row}] - \text{reach}$, sideways displacement becomes curl, and depth becomes $\text{depths}[\text{row}] - \text{drop}$. tipNormal uses the normalized endpoint tangent. Its vertical term is $-0.65 * \pi - 2 * \text{drop}$, because cosine at pi is -1. The tip UV is $(0.5, 1)$.

The final side loop takes each adjacent pair from the sixth sampled ring and joins them to the single apex. It contributes five triangles. There is no flat tiny cap at the tip and no set of five coincident endpoint vertices. There is also no cap at the attachment base; that open end starts against the funnel surface. Each tooth therefore has 31 vertices, 50 shaft triangles, and five tip triangles. Every tooth's base and tip keep its connectivity independent of the other 999 teeth.

The nested row and tooth loops close at lines 157-158. uploadMesh receives the aggregate vectors once and returns the teeth mesh at line 159; line 160 closes the function. This is one GPU mesh with 55000 triangles, not a thousand separate draw calls. The teeth do not deform individually after construction: the common head matrix moves, tilts, and radially scales all of them together.

Worm Pose and Attack Phases

Pose Fields and Terrain-Aware Head Position

****Source: arrakis_worm.h, lines 162-189.****

Pose contains head, a three-dimensional translation for the local mouth origin; tilt, an angle in radians used to tip the mouth and bend the body; and aperture, a radial scale for the mouth. There is no yaw field because heading is applied separately by a root matrix. The structure is an animation result, not persistent game state.

pose(center, attack, time, headingDegrees, approachProgress) accepts a worm center, an attack-phase time, the general animation time, and optional heading and approach progress defaulting to zero. The first three smooth transitions are rise over attack seconds 0-6, lunge over 6-12, and retreat over 13.5-18. These overlap only at endpoints and create distinct stages. Negative attack time gives zero for all three and represents approach.

ground=getDuneHeight(center.x, center.z) samples terrain beneath the center. The center's y value is not used as the head's terrain reference. approachHeight=10+4*smooth(0,1,approachProgress) raises the approaching head from ten to fourteen units above local terrain as progress advances. For negative attack time, this is the chosen height. For nonnegative attack time, the alternative is $14 + 22 * \text{rise} - 27 * \text{lunge}$: the head begins fourteen above ground, rises to 36, and lunges down to nine.

The next expression adds a 0.25-amplitude sine bob using $\text{time} * 1.6$, multiplied by rise and by $1 - \text{lunge}$. Bobbing fades in as the rise develops and fades out during the lunge. It does not oscillate the approach height because rise is zero before attack. `glm::mix(height, -24, retreat)` then pulls the head below terrain during retreat. The final target is 24 units below the sampled ground, not absolute world y -24.

Forward reach is $12 * \text{lunge} * (1 - \text{retreat})$. It grows to twelve during the lunge and disappears during retreat. Head is initially constructed at $(\text{center.x}, \text{ground} + \text{height}, \text{center.z} + \text{reach})$ in the unyawed deformation coordinate system. The later root matrix rotates that local +z reach toward the requested heading. This separation lets body and mouth geometry share a simple local bending plane.

Heading is converted from degrees to radians. A terrain target is sampled eighteen units from the center in the direction $(\sin(\text{heading}), \cos(\text{heading}))$ on the xz plane, and one unit is added to that height.

`aim = atan2(18 - reach, targetY - head.y)` is intentionally written with horizontal remaining distance as the first argument and vertical difference as the second. An ordinary yaw calculation would use a different interpretation; here the angle is measured away from the upward y direction into local +z. A target below the head therefore can produce a tilt greater than ninety degrees, tipping the mouth into a downward bite.

Tilt is $\text{radians}(70) * (1 - \text{rise}) + \text{aim} * \text{lunge} * (1 - \text{retreat})$. During approach it is seventy degrees. The rise removes that initial tilt, leaving an upright pose at attack six. The lunge adds the terrain-aware aim. Retreat fades the aim out. `swallow = smooth(12, 13.5, attack) * (1 - retreat)` narrows the mouth after the lunge and releases that narrowing during retreat. Aperture is $1 - 0.18 * \text{swallow}$, so the minimum intended radial scale is 0.82. Returning `{head, tilt, aperture}` uses aggregate initialization of the three fields.

At attack zero, height is fourteen and tilt seventy degrees. At six, height is 36 plus possible bob, reach is zero, and tilt is zero. At twelve, height is nine, reach is twelve, and tilt is the full aim, with swallow just starting. At 13.5, radial aperture is 0.82 and retreat has just begun. At eighteen, the formulas reach a submerged, untilted, reopened pose, but the public draw function rejects attack times at least eighteen, so that exact endpoint is not drawn. These are animation values rather than a separate collision model.

The Head Matrix and Order of Operations

****Source: `arrakis_worm.h`, lines 191-195.****

`headMatrix` begins with an identity matrix translated to `p.head`, then applies an x-axis rotation by tilt, then an xz radial scale $(\text{aperture}, 1, \text{aperture})$. With the renderer's usual column-vector convention, the resulting product is translation times rotation times scale. A local mouth vertex is radially scaled first, rotated second, and placed at the head third.

Scaling x and z but not y narrows the mouth and teeth arrangement without directly shortening its throat depths. An x-axis positive rotation transforms local up $(0, 1, 0)$ into $(0, \cos(\text{tilt}), \sin(\text{tilt}))$, exactly the axis used by body deformation. This agreement is what lets the body end meet the tilted lip. The function returns a matrix and does not bind a shader, change OpenGL state, or modify mesh vertices.

Deforming the Flexible Body

Neck Axis, Circular-Arc Centerline, and Buried Bezier Segment

****Source: `arrakis_worm.h`, lines 197-213.****

`deformBody(center, p)` changes the retained CPU vertex vector. It does not upload data by itself. It starts with the mouth's unit axis $(0, \cos(\text{tilt}), \sin(\text{tilt}))$. Neck length is 64 and join is 0.4. The body meets the rim at `end = p.head - 1.4 * axis`, placing its final centerline ring at the local mouth y of -1.4. That matches the first lip-profile point's height.

The `neckPoint(s)` lambda describes a constant-curvature neck rather than joining the head to the ground with a sharp corner. $\text{half} = 0.5 * \text{tilt} * (1 - s)$ is half the remaining angular sweep, and $\text{mid} = 0.5 * \text{tilt} * (1 + s)$ is the corresponding midpoint angle. `sinc` is $\sin(\text{half}) / \text{half}$ when half exceeds 0.0001 and one otherwise. The one branch avoids division by a nearly zero value and matches the limiting value of the expression for the normal

nonnegative tilt range used here.

The comparison is specifically $\text{half} > 0.0001$, not an absolute-value test. A negative tilt passed to this helper would take the one branch rather than evaluate its nonzero sinc, so it should not be described as a universally robust signed-arc implementation. The current approach and bite poses produce the nonnegative bending behavior the helper is designed for. This is a concrete implementation condition, not a source correction.

$\text{span} = 64 * (1 - s) * \text{sinc}$ is the straight chord distance associated with the remaining arc length. Subtracting $(0, \text{span} * \cos(\text{mid}), \text{span} * \sin(\text{mid}))$ from end gives the point on the circular arc. At s one, span is zero and the point is end. At s zero, it is the neck's lower endpoint. As tilt tends to zero, sinc tends to one and this becomes a straight upright 64-unit segment. The comment about a bend radius over twenty meters expresses the intent to keep a large smooth bend even during a downward bite; the geometry is not a thin hinged cylinder.

The lower body begins at $\text{p0} = (\text{center.x}, \text{terrainHeight} - 140, \text{center.z})$, deeply underground. $\text{p3} = \text{neckPoint}(0)$ is the connection to the visible curved neck. $\text{buriedLength} = (\text{p3.y} - \text{p0.y}) / 3$ defines vertical control offsets. $\text{p1} = \text{p0} + (0, \text{buriedLength}, 0)$ and $\text{p2} = \text{p3} - (0, \text{buriedLength}, 0)$ give a cubic Bezier segment vertical tangents at its ends while bridging any z displacement between the buried base and the curved neck's lower point. Only the upper part needs to be visually convincing; the deep base keeps the object from looking like a floating short tube when terrain or pose changes.

Ring Centers, Tangents, Radius, Ridges, and Surface Grain

****Source: arrakis_worm.h, lines 214-241.****

The j loop visits all 193 body rings. $t = j / \text{bodyRows}$ is the normalized longitudinal grid parameter. The code declares a center c and tangent for that ring and chooses one of two centerline formulas.

When t is below the join value 0.4, $s = t / \text{join}$ stretches the buried part onto a zero-to-one Bezier parameter, and $u = 1 - s$. Center c is the cubic combination $u^3 * \text{p0} + 3 * u^2 * s * \text{p1} + 3 * u * s^2 * \text{p2} + s^3 * \text{p3}$. Those coefficients form the familiar cubic Bezier curve. The tangent uses its derivative with the common factor of three removed: $u^2 * (\text{p1} - \text{p0}) + 2 * u * s * (\text{p2} - \text{p1}) + s^2 * (\text{p3} - \text{p2})$, then normalizes it. Removing that common positive factor does not change direction.

When t is at least 0.4, $s = (t - \text{join}) / (1 - \text{join})$ maps the rest of the body onto the neck arc. Center c comes from $\text{neckPoint}(s)$. Tangent is $(0, \cos(\text{tilt} * s), \sin(\text{tilt} * s))$, turning continuously from upward at the lower neck to the mouth's full tilt at the top. At the join, both constructions meet p3 and have an upward tangent, giving positional and directional continuity. Parameter speeds and sampling densities need not be identical; this is not a proof of equal arclength sampling for the whole body.

$\text{across} = (0, -\text{tangent.z}, \text{tangent.y})$ gives a perpendicular direction in the yz plane. The other cross-section direction is the x axis. Because the centerline remains in a fixed- x plane and tangent is normalized, these form a usable radial frame without constructing a full arbitrary three-dimensional transport frame.

$\text{taper} = 1 - \text{smooth}(0.85, 1, t)$ stays one through most of the body and falls to zero over the final fifteen percent of its parameter range. $\text{ridge} = 0.70 * \text{pow}(0.5 + 0.5 * \cos(2 * \pi * 32 * t), 3)$ creates 32 repeated ring ridges along t . The shifted cosine is in zero through one, cubing sharpens its peaks, and the coefficient limits ridge height to 0.70. The base body radius is consequently between 13.9 and 14.6 before the mouth blend and grain.

$\text{radius} = \text{mix}(13.9 + \text{ridge}, 15 * \text{aperture}, 1 - \text{taper})$ transitions from ridged skin to the mouth's 15-unit outer attachment radius, scaled by aperture. Far from the head, the mix weight is zero. At the final ring it is one, giving exactly the intended mouth-join radius in the mathematical formula. During swallowing, that final radius becomes 12.3 because 15 times 0.82 is 12.3. The skin therefore follows the narrowing mouth rather than remaining wide behind a shrunken lip.

For every ring, the i loop visits 97 angular positions including the duplicate seam. $a = 2 * \pi * i / \text{bodySlices}$ is the angle. $\text{radial} = (\cos(a), 0, 0) + \sin(a) * \text{across}$ combines the x direction and the transverse yz direction to generate a circle perpendicular to the current tangent. $\text{grain} = \text{taper} * (0.11 * \sin(13 * a + 9 * t) + 0.07 * \sin(29 * a - 17 * t))$ adds smaller irregularities with two angular frequencies and longitudinal phase changes. Its possible magnitude is at most about 0.18 when taper is one, and it fades away at the lip so the surfaces meet cleanly.

The vector index $j * (\text{bodySlices} + 1) + i$ accesses the existing body vertex rather than appending a new one. Position becomes $c + (\text{radius} + \text{grain}) * \text{radial}$. UV becomes $(i / \text{bodySlices}, t * 32)$, giving one wrap around the circumference and 32 repetitions along the body. The repeated longitudinal coordinate works with the renderer's procedural appearance; it is not a statement that the header loads a worm texture. Normals are deliberately left for a second pass because they depend on neighboring updated positions. Lines 240-241 finish the angular and longitudinal loops.

Finite-Difference Normals and Seam Copying

****Source: `arrakis_worm.h`, lines 242-256.****

The comment at line 242 explains the motivation for another normal method: a radial direction alone cannot account for changing ridges, taper, and bend. The next pair of loops recomputes normals from positional differences after every vertex position has been updated. The outer loop includes all body rings. The inner loop covers only the 96 unique angles, leaving the duplicated endpoint for an explicit copy afterward.

`prev=(i+bodySlices-1)%bodySlices` and `next=(i+1)%bodySlices` choose wrapped angular neighbors. At angle zero, the previous neighbor is 95 rather than an invalid -1; at 95, the next neighbor is zero. This uses the unique-angle set and avoids differentiating between the duplicated endpoint and its same-position counterpart.

The lower row neighbor is zero at the first row, otherwise $j-1$. The upper row neighbor is j at the final row, otherwise $j+1$. Interior rings therefore use differences across both sides, while end rings use one-sided differences. `ds` is the positional difference between higher and lower rows at the same angle; `da` is the positional difference between next and previous angles in the same row. Their cross product, `cross(ds, da)`, is normalized and assigned as the lighting normal.

The order matters. For a straight upward tube at its positive- x point, `ds` points up and `da` points roughly positive z , so `ds` crossed with `da` points outward positive x . Reversing the order would reverse the surface normal. Since these differences come from the full deformed positions, their directions include local grain, ring-ridge slope, radius change, and centerline bending. Dividing by the small parameter steps is unnecessary for the final direction because positive scalar factors vanish under normalization.

After each row's unique normals are finished, the last stored seam vertex receives the first vertex's normal exactly. This guarantees matching seam shading even if tiny trigonometric roundoff makes the nominally equal endpoint positions slightly different. This method is distinct from the lathe's accumulated triangle normals. There is no zero-vector check here either; it relies on the configured mesh and deformation producing valid neighbor directions. The final brace closes `deformBody` at line 256, and the internal namespace closes at 258.

Creating and Releasing All Worm Meshes

Cleanup and What It Resets

****Source: `arrakis_worm.h`, lines 260-265.****

`cleanupSandwormMeshes` brings the detail names into scope and calls `destroy` for body, lip, funnel, throat, and teeth. This releases fifteen possible GPU objects, three per mesh, and resets every mesh record. It then clears `bodyVertices` and sets both `ready` and `poseValid` false with a chained assignment.

Clearing the vector removes its active elements but normally retains its allocated capacity. Unlike the HUD's empty-vector swap, this cleanup does not explicitly shrink the retained CPU storage. The remembered center and animation floats are also not reset, but their cache is invalidated by `poseValid=false`, so stale values cannot suppress the next required upload. The routine can be called again on default mesh records because `destroy` tests each handle. It should run before destroying the context, and it makes no promise to restore all current draw bindings.

Body Allocation, Initial Pose, and Dynamic Storage

****Source: `arrakis_worm.h`, lines 267-279.****

`initSandwormMeshes` returns immediately when `ready` is true, avoiding duplicate creation. It resizes the CPU body vector to $(192+1) * (96+1) = 18721$ elements. `resize`, unlike `reserve`, creates the elements that the deformation

routine indexes. It then deforms this initial body at center zero using attack six and animation time zero. In that pose, rise is one, lunge and retreat are zero, tilt is zero, and the mouth is fully open. Terrain still contributes to the initial head's y; this is not necessarily a body centered vertically at world zero.

An empty local index vector receives the fixed grid connectivity, and `uploadMesh` creates the body VAO, VBO, and EBO. The scene upload helper initially supplies static buffer storage for ordinary meshes. The following block specifically replaces the body VBO's storage with `GL_DYNAMIC_DRAW`, using the full current CPU vector as data, because the body will change over time.

The code queries the current `GL_ARRAY_BUFFER_BINDING`, binds the body VBO, allocates dynamic storage using `bodyVertices.size()*sizeof(Vertex)`, and restores the queried binding. This is a narrow preservation block around the reallocation. It does not make the preceding `uploadMesh` state-transparent: that shared helper has its own binding behavior, including ending with VAO zero and leaving its array buffer bound. A reader should not assume this initialization has the HUD's broad `GLState` contract. Byte size is determined by `sizeof(Vertex)` so it remains correct if compiler alignment changes the record layout.

Exact Lip, Funnel, and Throat Profiles

****Source: `arrakis_worm.h`, lines 281-292.****

The lip has eight radius-height points and roughness 0.16. In profile order these are (15.0, -1.4), (15.6, -0.9), (15.9, -0.2), (15.5, 0.5), (14.8, 0.8), (14.0, 0.5), (13.4, -0.1), and (13.1, -0.8). The first attaches to the final body ring. Radius increases to a nominal maximum 15.9 around the outside, height peaks at 0.8, and the profile curls inward and down to the funnel's first point. This makes a thick rounded lip rather than a paper-thin circular edge. Interior roughness can shift radii slightly from these nominal values.

The funnel has fourteen points and roughness 0.08. Its exact ordered profile is (13.1, -0.8), (12.8, -1.3), (12.0, -2.0), (11.3, -2.6), (10.5, -3.5), (9.4, -4.5), (8.6, -5.4), (7.7, -6.3), (6.8, -7.3), (6.0, -8.2), (5.2, -9.2), (4.5, -10.1), (3.6, -11.4), and (2.9, -13.0). Both radius and height decrease, creating a deep narrowing cavity with inward-facing wall normals. The six tooth rows use the funnel points at radii 13.1, 11.3, 9.4, 7.7, 6.0, and 4.5 exactly. The lip-to-funnel and funnel-to-throat endpoints therefore agree by design.

The throat has five points, zero roughness, and the true-floor option enabled. Its profile is (2.9, -13.0), (2.6, -15.0), (2.2, -19.0), (1.7, -24.0), and (0.8, -27.0). It continues down another fourteen local units from the funnel's end and closes only at the narrow 0.8-radius bottom. There is no disc spanning the 13.1-radius mouth entrance. A dark material and genuine depth together make the opening look hollow rather than merely painted black.

At 160 angular slices, the lip's eight rings contain 1288 vertices and 2240 triangles. The funnel's fourteen rings contain 2254 vertices and 4160 triangles. The throat wall's five rings contain 805 vertices and 1280 triangles; adding a center and 161 copied ring vertices yields 967 vertices and 1440 triangles including the floor. These are exact topology counts for the current constants.

`teeth=makeTeeth()` completes the five meshes. `ready=true` marks initialization complete, while `poseValid=false` ensures the first real drawing input will trigger an upload even if it happens to match some remembered defaults. The function does not test individual upload results or recover from allocation failure; `ready` means the setup code finished, not that every GL operation was independently verified successful. The closed function at line 292 is the end of resource construction.

Together, the five meshes contain 54230 stored vertices and 99704 triangles: 36864 body, 2240 lip, 4160 funnel, 1440 throat, and 55000 tooth triangles. Duplicate seams and the independent floor rim count as stored vertices even when some positions coincide. The sand wake uses the renderer's existing sphere mesh and is not included in these totals.

Drawing, Cache Reuse, and Materials

Input Validation and Exact Pose-Cache Comparison

****Source: `arrakis_worm.h`, lines 294-316.****

`drawSandworm` accepts the center, attack time, animation time, optional heading degrees, and optional approach progress. It brings the detail namespace into local scope. The initial compound condition returns when resources are not ready; attack time or animation time is non-finite; any x, y, or z center component is non-finite; heading or approach progress is non-finite; or attack time is at least eighteen. Short-circuit evaluation stops at the first true disqualifier. Negative attack times are deliberately allowed because they display approach and its wake.

Although center y does not determine the terrain-based head height, the function still validates it and includes it in the cache. That makes the entire public position tuple consistently checked. It rejects non-finite progress before clamping it to zero through one. Pose calculation therefore sees a bounded approach progress. The pose is computed on every accepted draw, even when the body upload is cached, because the head matrix and wake still need current animation results.

The cache condition is true if the stored pose is invalid or any center component, attack time, animation time, heading, or clamped approach progress differs exactly from its remembered value. There is no epsilon threshold. A very small finite input change can cause a deformation and upload, while two passes using identical floats share the uploaded skin. Because time is included even when its bob contribution is currently zero, the cache may recompute geometry for some time changes that do not materially alter the body. It favors straightforward correctness over a phase-specific minimal key.

When the condition is true, `deformBody` updates all CPU positions and normals. The block saves the array-buffer binding, binds the body's VBO, and uses `glBufferSubData` to overwrite the full fixed-size vertex storage starting at byte zero. It does not orphan the buffer here, unlike the HUD's per-frame `glBufferData` strategy. The index buffer remains unchanged. The previous array-buffer binding is restored, then all input values are remembered and `poseValid` becomes true.

The comment at line 303 explains the render-pass motivation. A shadow pass and a normal scene pass should display the same pose. Only the flexible skin requires streaming; lip, funnel, throat, and teeth keep static vertex data and animate through model matrices. A second pass still makes the draw calls, but skips repeated CPU deformation and GPU data transfer when the input tuple matches.

The cache does not include a terrain version or terrain sample results. If `getDuneHeight` changed while all input floats stayed identical, the body cache could remain valid despite a changed height field, whereas the freshly computed head pose would reflect the query. In the current use, these terrain queries form a stable underlying height function; the tuple cache is not a general dependency-tracking system. Heading is included because it affects the terrain-aware target height, even though the final yaw is also performed by a matrix.

Five Material Records and Their Inheritance

****Source: `arrakis_worm.h`, lines 317-332.****

`skin` begins with the scene's default `Material`, then receives diffuse $(0.43, 0.27, 0.12)$, specular $(0.055, 0.04, 0.025)$, and shininess eight. These values describe a subdued brown exterior with weak, broad highlights. Default emissive color remains zero and default `isSand` remains zero. Brown coloration alone does not activate the renderer's terrain-sand shader branch.

`rim` copies `skin`, retaining its specular color, shininess, emissive setting, and non-sand flag, but raises diffuse to $(0.49, 0.31, 0.14)$. This makes the lip somewhat lighter without a wholly different reflection model. `inside` also copies `skin`, then uses darker diffuse $(0.15, 0.075, 0.029)$ and equal specular channels 0.018. The one-argument GLM vector constructor fills all three channels, so this is $(0.018, 0.018, 0.018)$, not only a red value.

`dark` copies `inside` and changes diffuse to $(0.009, 0.004, 0.002)$ with specular zero. It still inherits shininess eight, but zero specular makes that exponent irrelevant to a specular contribution. This nearly black throat material creates depth while keeping the actual geometry. `enamel` copies `skin`, uses diffuse $(0.58, 0.43, 0.24)$, equal specular channels 0.07, and shininess eighteen. The teeth are brighter and have more concentrated highlights than `skin` but are not pure white.

These material records are reconstructed on each accepted draw; they are cheap local descriptions rather than persistent GPU material objects. Their colors influence the normal scene pass through the shared renderer. In the

shadow pass the relevant geometry and transforms still matter, while the pass primarily writes depth and uses the renderer's shadow uniforms rather than displaying these RGB colors directly.

Rotation About the Worm Center and Five Draw Calls

****Source: `arrakis_worm.h`, lines 333-341.****

The root matrix starts with translation to center, then a y-axis rotation by the heading in radians, then translation by negative center. Its product is $T(\text{center}) * R_y(\text{heading}) * T(-\text{center})$. This rotates geometry about the worm's center rather than about world origin. It is necessary because the flexible body vertices have already been generated in coordinates positioned around center; applying an ordinary translation again would move them twice.

Positive heading rotates local +z toward positive x under GLM's usual right-handed convention. The pose target samples terrain along that same $(\sin(\text{heading}), \cos(\text{heading}))$ ground direction, so aiming and rendering agree. `head=root*headMatrix(p)` applies the local mouth aperture, tilt, and placement first, then the overall heading about center. This gives one shared mouth transform for all four static mouth pieces.

The five calls draw body with root and skin, lip with head and rim, funnel with head and inside, throat with head and dark, and teeth with head and enamel. The order is explicit and the mesh-material pairings are exact. They use the caller's active scene or shadow program through `drawMeshPrimitive`; `drawSandworm` does not create or choose its own shader. There is no separate translucent mouth pass, no tooth-by-tooth loop during drawing, and no dynamic mouth VBO upload.

Unlike `drawRescueHud`, this function has no broad OpenGL state guard. The common drawing helper binds each mesh VAO and leaves its normal renderer-side state behavior in place. The narrow array-buffer restoration inside the cache-update block is the only explicit binding preservation performed here. Calling the worm as part of both normal scene passes follows the renderer's existing conventions rather than treating it as an isolated overlay library.

The Moving Sand Wake

Wake Timing, Material, Positions, and Animated Scales

****Source: `arrakis_worm.h`, lines 342-358.****

`wake=1-smooth(0,6,attackTime)` is one throughout negative-time approach and fades to zero during the initial rise. The wake block executes only when wake exceeds 0.001. This suppresses tiny nearly vanished spheres as the rising worm emerges, and no wake is drawn once the rise has completed. It is not an additional mesh allocation or a particle system in this header.

sand copies skin, changes diffuse to $(0.68, 0.46, 0.22)$, and sets equal specular channels 0.015. It retains shininess eight, emissive zero, and `isSand=0`; the name describes the intended visual mound, not a request to apply the terrain's special sand flag.

The loop draws four mounds for `i` zero through three. An initial local position is $(\text{center.x}, \text{center.y}, \text{center.z}-14-14*i)$. Thus the centers are fourteen, 28, 42, and 56 units behind local +z movement. The code transforms this point with root and homogeneous w one to find its yawed world x and z. A point uses w one so translation participates; a direction would use w zero. This temporary world position is used for a terrain query, not directly as the final draw position.

`local.y` becomes terrain height at the yawed world xz minus 0.8. Because root's only net rotation is about y, world y equals local y after the paired center translations; replacing local y with this ground value therefore places the mound correctly even though the original center y was present in the first point. The -0.8 sinks each sphere into the dune so its visible top looks like disturbed sand rather than a sphere resting on the surface.

`mound=translate(root, local)` composes the root with the mound translation. Scaling then uses x extent $(12-i)*\text{wake}$, y extent $(3+0.35*\sin(\text{time}*2-i))*\text{wake}$, and z extent $10*\text{wake}$. The four x scales are twelve, eleven, ten, and nine times wake. Vertical scale oscillates between 2.65 and 3.35 times wake, with each mound phase offset by `i`. The z scale is uniformly ten times wake. When wake approaches zero, all three dimensions shrink together.

The final call draws the already-existing `g_meshSphere` with that mound matrix and sand material. Four transformed spheres create a stylized raised wake using shared geometry. Their actual geometric radii depend on the renderer's sphere primitive definition; these numbers are model scale factors, not an independently asserted sphere radius. The positions rotate with heading, stay terrain-aware, and pulse with animation time. Lines 356-358 close the loop, conditional wake block, and drawing function.

End of Header and Lifecycle Summary

****Source: `arrakis_worm.h`, line 360.****

The final preprocessor directive closes the guard begun at lines 1-2. The complete lifecycle is initialization while the context is current, repeated validated calls in both render passes, and cleanup before context destruction. CPU construction happens once for static mouth geometry; CPU skin deformation and VBO updates happen only when the cached pose inputs change. All five worm meshes are explicitly destroyed, while the shared sphere belongs to the surrounding renderer and is not deleted by worm cleanup.

Numerical and Design Checks

Following One HUD Frame From State to Pixels

The input snapshot remains `const` throughout composition. On a 1280-by-720 framebuffer, `scale` is one and the noncompact desktop layout applies. Its margin is 22, inner width is 1236, top card height is 106, and normal radar top is 160. The control string wraps according to its 1.5-unit pixel font, and the bottom cards' positions depend on the resulting line counts. These dependencies explain why the radar is measured after the action card rather than assigned an unconditional fixed y-to-bottom region.

On a 640-by-360 framebuffer, `scale` is still one, margin is ten, and `compact` is true. Because `shortView` tests strictly less than 360, height exactly 360 is compact but not short. Its top card is therefore 112 high rather than 78. On height 359, `shortView` becomes true and the special side-radar conditions become eligible. Strict threshold details matter when checking screenshots at boundary sizes; `w<760`, `h<440`, and `h<360` do not include their equality values.

On a 2560-by-1440 framebuffer, `scale two` produces the same 1280-by-720 layout dimensions as the desktop example while increasing physical glyph and line thickness. This is why the width and height uniform must use `w` and `h` rather than the raw framebuffer dimensions: the viewport already maps the clip-space result to the actual framebuffer. Using raw framebuffer dimensions in the shader after scaled composition would incorrectly compress the HUD into part of the image.

The HUD also keeps display roles separate. `number` handles negative integer counts, `clock` handles bounded upward-rounded time, `decimal` handles bounded zero-decimal measurements, `unit` handles bar fractions, and `finite` handles individual floating-point values. Not all conditions sanitize inputs before comparing them. The explicit finite checks and fallback policies described above should therefore not be generalized into a claim that every imaginable corrupted snapshot is completely layout-safe.

Following One Worm Pose Through Both Passes

Suppose the caller draws a finite, initialized worm at attack six with time zero. Rise is one, lunge zero, retreat zero, aperture one, and tilt zero. The head lies 36 units above terrain. The body final ring is 1.4 units below that head along the upward axis and has radius fifteen, matching the lip's first profile ring. The neck is a straight 64-unit centerline segment in this pose because the arc sweep is zero. The buried Bezier segment joins it to a base 140 units below terrain.

If `poseValid` is false, the first pass deforms 18721 vertices, computes their normals, and uploads the complete body VBO. The other four meshes are already static. Five mesh draw calls render the worm; the wake is zero at attack six, so no mound spheres are drawn. If the second pass receives exactly the same center, attack, time, heading, and clamped progress, it calculates the pose again but skips body deformation and upload. It still issues the same five mesh draws with the appropriate caller-selected shader pass.

On a later attack value, changing the body skin and multiplying static mouth vertices by the current head matrix produce coordinated motion. The root rotates the full assembly toward heading. The body normals are recomputed from its bent surface, while the static mouth and tooth normals are transformed by the scene shader's normal-transform machinery. When attack reaches eighteen, the validation branch returns before any material setup or draw calls. Visibility termination is therefore explicit, not merely the result of the worm becoming dark or moving beneath dunes.

Limitations That Should Not Be Mistaken for Features

The HUD has a fixed ASCII bitmap vocabulary rather than Unicode typography, no mouse-click buttons, no input event handling, no texture atlas, and no automatic count reconciliation. The layouts adapt by wrapping, reducing sizes, changing placements, and omitting secondary panels, but they do not implement scrolling for impossibly small framebuffers. The unsupported apostrophe and brackets are real fallback behavior. The declared pickup position and centered-text helper are unused in this header.

The worm does not load `sandworm.jpg`, import a model, regenerate a random set of teeth every frame, or animate each tooth separately. It has five owned meshes and reuses a scene sphere for the wake. It uses a fixed topology, deterministic sinusoidal irregularity, a circular-arc visible neck, a buried cubic Bezier transition, and a tuple cache. There is no general OpenGL state guard, no upload error recovery, no terrain-version cache key, and no automatic initialization inside `drawSandworm`. These boundaries help distinguish what the code really guarantees from what a reader might infer from the visual result.

Complete Source Coverage Index

The intervals below are an audit of the explanation, not an additional source listing. Every nonblank line in the original two headers is included in an explained region. Structural lines such as opening and closing braces, namespace boundaries, return statements, comments, and end guards belong to the cited region containing the construction they complete. Blank separators do not carry operations.

Original Header	Line Range	Explained Region
<code>arrakis_hud.h</code>	1-28	Include guard, all includes, every <code>RescueHudState</code> member, defaults, and the outside-crew comment.
<code>arrakis_hud.h</code>	30-34	Current-context contract, framebuffer coordinates, preservation contract, and internal namespace opening.
<code>arrakis_hud.h</code>	36-52	Every palette constant, both internal structs, and the static resource accessor.
<code>arrakis_hud.h</code>	53-66	Finiteness, normalized clamping, count strings, rounded values, and countdown formatting.
<code>arrakis_hud.h</code>	68-90	Every saved-state field, capability entry, GL query, and constructor loop.
<code>arrakis_hud.h</code>	91-107	All restoration calls, branches, destructor behavior, and deleted copy operations.
<code>arrakis_hud.h</code>	109-124	Shader creation, compilation, status, diagnostics, failure deletion, and successful return.
<code>arrakis_hud.h</code>	126-147	Triangle, rectangle, border, card, and progress-bar construction.
<code>arrakis_hud.h</code>	149-204	Font comment, all 50 explicit glyph cases, default case, and five-bit encoding.

Original Header	Line Range	Explained Region
arrakis_hud.h	205-222	Text width, case conversion, each font scan branch, run merging, and character advance.
arrakis_hud.h	223-247	Width-to-column expression, lambda, word splitting, whitespace/newline behavior, and returned lines.
arrakis_hud.h	248-255	Centered placement, line-count cap, and line-loop spacing.
arrakis_hud.h	257-294	Radar card, grid, coordinate clamp/map, all marker branches, marker order, and every legend.
arrakis_hud.h	296-322	Overlay dimming, precedence, responsive dimensions, every body/key string, and panel placement.
arrakis_hud.h	323-341	Branding, heading, all result rows, cursor increments, body, separator, and keys.
arrakis_hud.h	343-355	Margin, modes, extraction timer, duration defense, warning decisions, and top-card size.
arrakis_hud.h	356-375	All desktop header labels, coordinates, seat loop, counts, countdown, and bar.
arrakis_hud.h	375-392	Compact branch, right alignment, short-view placements, omitted rows, and compact seats.
arrakis_hud.h	394-422	Controls string and wrap, action precedence, side-radar test, truncation, card, and shared progress.
arrakis_hud.h	424-442	Radar sizing and labels, telemetry gates, every measurement/string, boost, and pursuit.
arrakis_hud.h	443-452	Flight-only guide condition, four corner loops, offsets, and final overlay call.
arrakis_hud.h	454	Internal namespace closure.
arrakis_hud.h	456-491	Public initializer, GLSL expressions, shader and program creation, all compilation/link failure paths.
arrakis_hud.h	492-510	Binding queries, VAO/VBO allocation failure, uniform location, vertex attributes, restore, and CPU reserve.
arrakis_hud.h	512-540	Dimension checks, lazy init, scope guard, scale, composition, drawing state, buffer growth/orphaning, upload, draw.
arrakis_hud.h	542-552	Conditional resource deletion, resets, CPU capacity release, function end, and guard end.
arrakis_worm.h	1-20	Guard, comments, dependencies, namespace, all constants, meshes, CPU vector, flags, and cached values.
arrakis_worm.h	22-32	Smoothstep expression and conditional mesh deletion/reset.

Original Header	Line Range	Explained Region
arrakis_worm.h	34-43	Grid capacity, both loops, all corner-index expressions, triangle order, and closure.
arrakis_worm.h	45-61	Normal reset, triangle accumulation, seam loop, normalization, and assumptions.
arrakis_worm.h	63-84	Winding comments, lathe parameters, sampling loops, complete roughness formula, positions, UVs, connectivity, normals.
arrakis_worm.h	85-97	Deep-floor branch, center, copied rim, triangle fan, normals, upload, and function closure.
arrakis_worm.h	99-120	All tooth constants and arrays, exact capacity expressions, row/tooth loops, seed, angles, variation, dimensions, base.
arrakis_worm.h	121-137	Ring loop, centerline, derivative, frame vectors, taper exponent, side loop, vertex data, and loop closure.
arrakis_worm.h	138-160	Side connections, modulo, apex comment, exact tip position/normal/UV, final triangles, loops, and upload return.
arrakis_worm.h	162-189	Every pose field, all timed transitions, terrain samples, heights, bobbing, reach, aim, tilt, swallowing, and return.
arrakis_worm.h	191-195	Head translation, rotation, aperture scale, returned product, and closure.
arrakis_worm.h	197-213	Mouth axis, neck constants, end, arc lambda and small-angle branch, buried endpoints and control points.
arrakis_worm.h	214-241	All body rings, Bezier/arc branch, tangent, radial frame, taper, ridge, blend, grain, position and UV expressions.
arrakis_worm.h	242-256	Normal comment, both derivative loops, wrapped neighbors, endpoint branches, differences, cross product, seam, closure.
arrakis_worm.h	258	Internal namespace closure.
arrakis_worm.h	260-265	Public cleanup, all five destroys, CPU clear, and flag invalidation.
arrakis_worm.h	267-279	Idempotence, body size, initial pose, grid/upload, dynamic reallocation, and narrow binding preservation.
arrakis_worm.h	281-292	Every exact profile point, roughness, throat floor, teeth creation, ready/cache flags, and closure.
arrakis_worm.h	294-316	Public parameters, every validation term, clamp, pose, exact cache condition, deformation, upload, restore, and cache updates.
arrakis_worm.h	317-332	All five materials, every diffuse/specular/shininess number, and inherited defaults.

Original Header	Line Range	Explained Region
arrakis_worm.h	333-341	Root pivot transforms, heading conversion, head product, and all five mesh-material draws.
arrakis_worm.h	342-358	Wake transition and threshold, sand material, four-mound loop, terrain alignment, all scale factors, sphere draws, and closures.
arrakis_worm.h	360	Guard end.

The chapter covers 552 original HUD lines and 360 original worm lines, or 912 total source lines including blank separators. The HUD contains 533 nonblank lines and the worm contains 341, giving 874 nonblank lines in total. A mechanical comparison of the relocated headers against this coverage index found no uncovered nonblank lines in either file. The coverage index assigns every nonblank source line to explanatory prose or the exact glyph table. No complete code listing is embedded here; the complete source appendix can be appended separately without replacing these explanations.

6. Spatial Audio and Vendor Implementations

6.1 Scope, Versions, and Reading Conventions

This chapter explains the complete Arrakis audio wrapper and the architecture of the supplied audio and OpenGL vendor implementations. The gameplay code chooses events, positions, pitch, and volume. miniaudio performs decoding, channel conversion, resampling, spatialization, mixing, and delivery to an operating-system audio device. GLAD performs a completely different task: discovering OpenGL capabilities and resolving graphics-driver entry points. The formerly bundled stb_vorbis source was unused and has been removed during cleanup; its historical architecture is discussed separately to explain the unintegrated Ogg fallback, not as remaining executable or appendix code.

The source was reorganized while this documentation was prepared. Audio references give the final organized line numbers as well as explicitly marked original numbers for historical comparison. The source appendix contains current remaining code, not the removed Vorbis file. Vendor implementation line numbers are unchanged except for GLAD's final blank line. Audio lines after the old search-directory list moved upward by two lines. Function names and the tables below are the primary navigation keys if later edits change line numbers.

Source	Organized location	Original line total	Inspected organized line total	Build role
arrakis_audio.h	src/arrakis_audio.h	295	293	Header-only gameplay audio wrapper; one C++17 inline global
miniaudio_impl.cpp	third_party/miniaudio/miniaudio_impl.cpp	2	2	Emits the miniaudio implementation in exactly one translation unit
miniaudio.h	third_party/miniaudio/miniaudio.h	95,864	95,864	miniaudio 0.11.25, dated 2026-03-04; includes embedded decoder implementations
glad.c	third_party/glad/glad.c	1,833	1,832	GLAD 0.1.36-generated OpenGL 4.6 core loader, generated 2026-09-11
stb_vorbis.c	Removed unused root-level source, inspected before cleanup	5,584	Removed	Historical stb_vorbis 1.22; never integrated into this executable

The chapter supplies complete, contiguous line-coverage maps and explanatory sections for the vendor functional families. It does **not** pretend that an architectural explanation is a separate semantic annotation of every one of miniaudio's 95,864 lines, or a security audit of all platform branches. The numbered source appendix is the exact-code companion for remaining project code. Use the family explanations here, the declaration/definition index strategy in Section 6.10, and the current source listings together when reading an individual vendor function. An unused backend, declaration, table, generated assignment, comment, or license is still accounted for in the coverage maps; being accounted for does not mean it executes in this Windows game. Historical Vorbis ranges are separate from current-source coverage.

6.2 arrakis_audio.h: Includes, File Lookup, and State

6.2.1 Includes and Linkage

Original lines 1-9, also organized lines 1-9, contain `#pragma once` and the dependency includes. The `pragma` prevents repeated definitions within one translation unit. `miniaudio.h` provides the engine, sound objects, result types, and C-compatible audio API. GLM supplies `glm::vec3`, length, normalization, clamp, and mix operations. `<string>` stores paths; `<vector>` stores ordered search directories and candidates; `<fstream>` probes readability; `<iostream>` prints status messages; `<algorithm>` is included but has no directly named algorithm invocation in this header.

The wrapper uses `std::exp` and `rand()` without directly including `<cmath>` and `<cstdlib>` here. Their availability currently depends on the surrounding include environment. This is an include-hygiene observation, not a claim that this documentation changed the header. No vendor or wrapper implementation is edited by this chapter.

The free function `findSoundFile` is `inline`, and methods defined inside `ArrakisAudio` are implicitly `inline`. Original line 295, now line 293, declares `inline ArrakisAudio g_audio;`. Under C++17 this is one program-wide global object rather than a separate audio engine per including translation unit. Its aggregate/default member initializers prepare storage and flags; they do not initialize an operating-system device.

Final lines 291-293 close the `ArrakisAudio` structure with a brace and semicolon, then define that global instance. The semicolon finishes the type declaration; the following object definition creates the shared owner used by input, mission, and runtime code. The intervening blank line only separates those declarations visually.

6.2.2 findSoundFile(filename)

Final lines 11-25; original lines 11-27.

The sole parameter is `const std::string& filename`: a read-only filename reference, normally without a directory component. The return value is either the first readable relative path or an empty string. The function neither decodes the file nor establishes that its contents are valid audio.

The **current organized search order** is exact:

1. `assets/audio/`
2. `../assets/audio/`
3. `../../assets/audio/`
4. `../../../assets/audio/`
5. `../../../../assets/audio/`

The **original search order**, recorded only for older laboratory launches and the cleanup change, was:

1. `sounds/`
2. `../sounds/`
3. `../../sounds/`
4. `../../../sounds/`
5. `sounds/kenney_interface-sounds/Audio/`
6. `../sounds/kenney_interface-sounds/Audio/`
7. `"",` meaning the current working directory itself.

The organized implementation no longer searches a Kenney subdirectory or the bare current working directory. A relative directory is resolved against the **process working directory**, not the header's location or necessarily the executable's directory. The revised CMake post-build command copies `assets/audio` under `$(TARGET_FILE_DIR:Arrakis)/assets/audio` and sets the Visual Studio debugger working directory to the

executable directory; this makes the first candidate usable for normal configured IDE launches. Independently launching the executable from an unrelated directory can still make all five probes fail.

`static const std::vector<std::string> searchDirs` is initialized once and reused. The range-for binds `dir` as `const auto&`, avoiding string copies. `path = dir + filename` constructs one candidate. `std::ifstream f(path.c_str())` opens the path for input; `f.good()` checks the stream state. Success returns immediately, with the local stream closed by its destructor. On failure the loop moves to the next directory; after exhaustion it returns `""`.

There is no cache, filesystem canonicalization, absolute-path asset root, extension validation, binary content test, recursive search, or diagnostic for individual lookup failures. Each call can perform five filesystem probes in the organized layout. Importantly, it returns the first readable instance of a **particular filename**. If that file later fails audio decoding, `loadSound` advances to a different candidate filename; it does not ask `findSoundFile` to try a second directory containing the same filename. A corrupt nearer copy can therefore shadow a valid farther copy.

6.2.3 Every ArrakisAudio Field

Final lines 27-60; original lines 29-62.

Field	Initial value	Meaning and lifetime
<code>ma_engine engine</code>	<code>{}</code>	Stable, zero-initialized storage for the high-level engine, graph, listeners, and pointers to device/resource-manager state. Must be initialized before engine API use and uninitialized after dependent sounds.
<code>initialized</code>	<code>false</code>	Records successful engine initialization. Guards update and shutdown; does not mean every optional sound loaded.
<code>muted</code>	<code>false</code>	User's requested mute state. Persists across mission resets and is displayed by the HUD.
<code>masterVolume</code>	<code>1.0f</code>	Linear engine gain restored on active, unmuted updates. 1 is unity, not a percentage in decibels. No local clamp or UI adjustment is implemented.
<code>sndFlight</code>	<code>{}</code>	Flight-loop sound instance, located at the ornithopter; pitch changes with flight speed.
<code>sndBoost</code>	<code>{}</code>	Continuously started boost loop, made audible by smoothed volume.
<code>sndWormRumble</code>	<code>{}</code>	Worm-position rumble loop; controlled by mission phase, attack time, and proximity.
<code>sndWormBreach</code>	<code>{}</code>	Single reusable eruption/roar sound instance. A mission latch permits one trigger.
<code>sndRescueWinch</code>	<code>{}</code>	Single reusable pickup/winch one-shot located at the ornithopter.
<code>sndRescueSafe</code>	<code>{}</code>	Single reusable successful-delivery one-shot located at the base.
<code>sndHarvester</code>	<code>{}</code>	Harvester movement loop located at the crawler.
<code>sndCrewHelp</code>	<code>{}</code>	Single reusable periodic crew-help one-shot located at the nearest selected crew member.

Field	Initial value	Meaning and lifetime
hasFlight	false	sndFlight successfully initialized; permits its updates and uninitialization.
hasBoost	false	Equivalent validity flag for sndBoost.
hasWormRumble	false	Equivalent validity flag for sndWormRumble.
hasWormBreach	false	Equivalent validity flag for sndWormBreach.
hasRescueWinch	false	Equivalent validity flag for sndRescueWinch.
hasRescueSafe	false	Equivalent validity flag for sndRescueSafe.
hasHarvester	false	Equivalent validity flag for sndHarvester.
hasCrewHelp	false	Equivalent validity flag for sndCrewHelp.
boostVolume	0.0f	Application-side smoothed boost gain. Changes only when a boost sound exists and update passes its early guards.
flightPitch	1.0f	Application-side smoothed playback-rate/pitch multiplier. Changes only for a loaded flight sound.
crewHelpTimer	3.0f	Seconds until the next proximity check/call. Decrement only while flying, loaded, unpaused, and unmuted.
breachTriggered	false	Once-per-mission breach latch. Reset by resetMission, not by the sound ending.
lastRescued	0	Previous processed rescued count, used for positive delivery edges.
lastAboard	0	Previous processed aboard count, used for positive pickup edges.
lastPickup	0.0f	Previous processed pickup-progress value, used for a threshold crossing.

Each sound has exactly one `ma_sound`, so retriggering the same cue restarts or seeks that voice; it does not allocate overlapping copies. The structs own internal pointers and participate in a live graph. Do not copy, move, or `memset` initialized engine/sound objects. The global's stable address satisfies miniaudio's object-address lifetime requirement.

6.3 Initialization, Lambda, Candidates, and Optional Assets

6.3.1 `init()` and the Silent-Mode Branch

Final lines 62-129; original lines 64-131. No parameters. The boolean return reports engine creation, not complete asset availability.

`ma_engine_config config = ma_engine_config_init()` uses vendor defaults instead of manually zeroing a configuration. `ma_engine_init(&config, &engine)` returns a `ma_result`. If it is not `MA_SUCCESS`, the wrapper writes exactly the warning prefix `[AUDIO] Warning: Failed to initialize audio engine (code: , the numeric result, and )`. Running in silent mode., sets `initialized = false`, and returns `false`. The game calls `g_audio.init()` without aborting on its return, making hardware failure nonfatal to rendering and mission logic. Later update calls immediately return in this mode.

Success sets `initialized = true`. `ma_engine_listener_set_world_up(&engine, 0, 0, 1, 0)` means listener **index 0**, then world-up components **(0, 1, 0)**. The two initial zeros have different meanings; this does not set an up vector of `(0, 0, 1)`. The game uses a Y-up world.

Default engine configuration creates one listener, a playback device unless explicitly disabled, and an internal resource manager unless supplied by the caller. The vendor engine normally auto-starts its device; individual sounds remain stopped until their own start calls. Channels and sample rate are negotiated with the device rather than hardcoded by Arrakis. The library's generic defaults include f32, two channels, 48,000 Hz, three periods, and 10 ms low-latency/100 ms conservative period sizes, but those are fallback/configuration defaults, not proof of the actual runtime endpoint format or latency.

`init()` has no already-initialized guard. Calling it twice without shutdown is not a supported wrapper lifecycle: it can overwrite live vendor objects. It also does not apply a preexisting muted state at initialization, so the normal frame update is responsible for enforcing it.

6.3.2 The `loadSound Lambda`

Final lines 75-91; original lines 77-93.

[this] captures the owning `ArrakisAudio*`, allowing the lambda to use engine. It is local to `init`, invoked immediately for each sound, and never escapes into an asynchronous callback. The trailing `-> bool` declares its explicit result type. The initializer-list arguments construct temporary candidate vectors valid for each call.

Parameter	Exact type	Purpose
<code>snd</code>	<code>ma_sound*</code>	Address of the destination sound storage.
<code>candidates</code>	<code>const std::vector<std::string>&</code>	Ordered filename alternatives; first successfully decoded/initialized candidate wins.
<code>loop</code>	<code>bool</code>	Converted to miniaudio's <code>MA_TRUE/MA_FALSE</code> loop setting.
<code>minDist</code>	<code>float</code>	Reference/minimum attenuation distance in the game's coordinate units.
<code>maxDist</code>	<code>float</code>	Maximum distance used by the clamped attenuation model, not an automatic cutoff radius.
<code>model</code>	<code>ma_attenuation_model</code>	Defaults to <code>ma_attenuation_model_inverse</code> ; some calls repeat this explicitly.

For each `const auto& name`, it calls `findSoundFile(name)`. An empty result skips initialization. A nonempty path is passed to `ma_sound_init_from_file(&engine, path.c_str(), 0, nullptr, nullptr, snd)`. Its six arguments mean engine owner, narrow-character path, **flags 0**, no initial sound group, no completion fence, and output sound storage.

Flags 0 do not request streaming, asynchronous loading, predecoded PCM, disabled pitch, disabled spatialization, or detached graph placement. The resource manager's normal non-streaming path loads encoded data into memory and makes a decoder-backed data source; decoding/conversion can occur during reads. Vendor sound initialization internally adds a wait-for-initialization requirement so the sound's data format is known. This is not the same as setting `MA_SOUND_FLAG_DECODE` to predecode an entire MP3 file.

If `r == MA_SUCCESS`, the lambda sets looping, minimum distance, maximum distance, and attenuation model in that order, prints `[AUDIO] Loaded:` followed by the selected path, and returns `true`. If initialization fails, it silently continues to the next candidate. There is no per-candidate decode error report and no assertion that filename existence implies codec support. Exhaustion returns `false`, which becomes the relevant `has*` flag. Vendor initialization handles its internal failure cleanup; the wrapper never uninitialized a sound that did not report successful creation.

6.3.3 Complete Sound-Candidate and Constant Table

All filename orderings are literal and significant. Every sound uses inverse-distance attenuation, whether supplied explicitly or by the lambda default.

Cue; final lines	Candidates in exact order	Loop	Minimum / maximum distance	Initial sound gain	Initial playback
Flight; 93-95	ornithopter_flight.mp3, ornithopter_flight.wav	Yes	12.0f / 150.0f	0.75f	Stopped; first active update starts it
Boost; 97-102	ornithopter_boost.mp3, ornithopter_boost.wav	Yes	12.0f / 150.0f	0.0f	Started immediately, initially inaudible
Worm rumble; 104-106	worm_rumble.mp3, worm_rumble.wav	Yes	30.0f / 320.0f	0.9f	Stopped
Worm breach; 108-110	worm_breach.mp3, worm_breach.wav	No	45.0f / 380.0f	1.0f	Stopped
Harvester; 112-114	harvester_engine.wav, harvester_engine.mp3, harvester.wav	Yes	18.0f / 200.0f	0.75f	Stopped
Winch; 116-118	rescue_winch.wav, rescue_winch.mp3	No	15.0f / 120.0f	0.85f	Stopped
Safe delivery; 120-122	rescue_safe.wav, rescue_safe.ogg, rescue_safe.mp3, confirmation_004.ogg	No	20.0f / 140.0f	0.95f	Stopped
Crew help; 124-126	crew_help.wav, crew_help.mp3, question_001.ogg	No	16.0f / 85.0f	0.85f	Stopped

Original lines for these calls are two greater than the final numbers. `if (has . . .)` guards every initial volume assignment and the boost start. The final `return true` occurs even if **all eight files fail** after the engine succeeded. That separation intentionally permits a partly or wholly silent asset configuration.

6.3.4 What Is Present and What Is Optional or Absent

The organized active asset folder `assets/audio/` contains all eight preferred files:

- `ornithopter_flight.mp3`
- `ornithopter_boost.mp3`
- `worm_rumble.mp3`
- `worm_breach.mp3`
- `harvester_engine.wav`
- `rescue_winch.wav`
- `rescue_safe.wav`

- crew_help.wav

The following alternative candidate names were **not present in the inspected active folder**:

ornithopter_flight.wav, ornithopter_boost.wav, worm_rumble.wav, worm_breach.wav, harvester_engine.mp3, harvester.wav, rescue_winch.mp3, rescue_safe.ogg, rescue_safe.mp3, confirmation_004.ogg, crew_help.mp3, and question_001.ogg. They are optional fallback names, not mandatory missing dependencies. Adding one is useful only if its format is supported and it is placed in a searched directory.

Before reorganization the wider sounds/ tree did include rescue_safe.ogg and Kenney Audio/confirmation_004.ogg and Audio/question_001.ogg, along with many unused Kenney interface clips. Those duplicate/unused Ogg assets were removed during cleanup while the eight active files and license were retained. A separately supplied old/external pack would not be discovered unless its files were placed in the organized searched asset locations. More importantly, the current miniaudio implementation does not enable Vorbis decoding, so a discoverable .ogg fallback still would not become playable just because its file exists. The primary WAV/MP3 cues avoid this issue.

assets/audio/Kenney-License.txt is attribution/license material, not a decoded cue. Asset presence was established by filename inspection, not by listening to every file, proving its binary encoding, or validating the semantic content implied by names such as crew_help.wav. Runtime load success is a separate check.

6.4 update: Parameters, Math, Every Branch, and Event Semantics

6.4.1 Complete Parameter Contract

Final lines 137-154; original lines 139-156. The function returns void; it consumes a snapshot rather than querying mission globals itself.

Parameter	Type	Meaning and actual caller input
dt	float	Frame time in seconds. Used by exponential smoothing and crew timer; not a count of audio samples.
camPos	const glm::vec3&	Smoothed camera eye position; becomes listener position.
camTarget	const glm::vec3&	Smoothed camera target; determines listener forward vector.
ornPos	const glm::vec3&	Ornithopter position, used by flight, boost, and pickup sounds.
ornSpeed	float	Ornithopter speed scalar; drives artificial flight pitch rather than velocity-based Doppler.
isBoosting	bool	Boost-input/gameplay state; reduces flight-loop gain and can raise boost-loop gain.
harvPos	const glm::vec3&	harvesterPosition(); harvester sound origin.
wormPos	const glm::vec3&	wormPosition(); rumble origin and breach origin at trigger time.
wormDist	float	wormGap(); a gameplay separation measure driving extra rumble modulation. It is not the listener-source distance calculated by miniaudio.

Parameter	Type	Meaning and actual caller input
attackTime	float	wormAttackTime(), defined as mission elapsed time minus breachAt; negative before breach and nonnegative afterward.
rescuedCount	int	Cumulative delivered crew; an increase causes a safe-delivery cue.
aboardCount	int	Current onboard crew; an increase causes a pickup cue.
pickupProgress	float	Current winch/pickup progress; the upward crossing of 0.08f causes a pickup cue.
nearestCrewPos	const glm::vec3&	nearestCrewPosition(); selected help-call origin.
nearestCrewDist	float	Caller computes horizontalDistance(g_ornPos, nearestCrewAudio); this is horizontal ornithopter-to-crew distance, not camera distance.
basePos	const glm::vec3&	Mission base position; safe-delivery sound origin.
isFlying	bool	Exact test g_mission.phase == MissionPhase::Flying; not inferred from speed or altitude.
isPaused	bool	Mission pause flag; suppresses master output and further wrapper processing.

The original call is in `arrakis.cpp` lines 1683-1703. Position references are borrowed for this call only. `miniaudio` setters copy scalar/vector values into its objects; the audio callback does not retain references to these temporary snapshot arguments.

6.4.2 Engine Guard, Pause, and Mute

Final lines 155-164; original lines 157-166. The opening brace begins the update body; its matching close is final line 268.

If `!initialized`, return without touching vendor state. Otherwise, if `isPaused || muted`, set engine gain to `0.0f` and return. The else path restores `masterVolume` every active frame.

This is **output muting, not transport pausing**. The engine/device is not stopped, sound objects are not stopped, decoder cursors can continue, and a playing one-shot can finish inaudibly. The early return also freezes the wrapper's listener updates, pitch/boost interpolation, crew-help timer, breach latch processing, and `last*` snapshots. When unmuting, count differences accumulated during silence may cause delayed winch or delivery triggers. A breach occurring entirely outside the `0 ≤ attackTime < 2.5` interval while muted can be missed permanently. Pause normally also pauses mission progression elsewhere, whereas mute alone does not.

6.4.3 Listener Direction

Final lines 166-172; original lines 168-174.

`look = camTarget - camPos` constructs the camera forward displacement. If `glm::length(look) > 0.001f`, it is normalized to unit length. Otherwise `look = glm::vec3(0, 0, -1)` provides a valid negative-Z forward direction rather than dividing an almost-zero vector by its length. Equality at exactly `0.001f` takes the fallback branch.

`ma_engine_listener_set_position(&engine, 0, camPos.x, camPos.y, camPos.z)` and `ma_engine_listener_set_direction(&engine, 0, look.x, look.y, look.z)` both target listener zero.

Camera movement changes perceived panning/attenuation even when gameplay objects do not move. No listener velocity or source velocity is supplied, so the library's Doppler capability is not driven by the game's actual velocities.

6.4.4 Exponential Smoothing, with Exact Interpretation

The flight and boost branches use `glm::mix(current, target, 1 - exp(-k*dt))`. For scalars, mix is $(1-a)*current + a*target$. Therefore the update is:

```
a = 1 - exp(-k * dt)
next = target + (current - target) * exp(-k * dt)
```

For constant targets and nonnegative finite `dt`, the remaining error decays exponentially, and successive updates compose by elapsed time. This is more frame-rate-independent than using `k*dt` directly as an unclamped lerp weight. `dt = 0` changes nothing; large positive `dt` approaches the target without overshoot. Negative `dt` yields a negative interpolation weight and moves away from the target; the wrapper does not validate it. NaNs/infinities likewise are not rejected here.

The flight rate is `k = 6.0f`, time constant $1/6$ second and half-life $\ln(2)/6$, approximately 0.1155 seconds. The boost rate is `k = 8.0f`, time constant 0.125 seconds and half-life about 0.0866 seconds. At 60 Hz, the weights are approximately 0.09516 and 0.12483 . These application-side states are distinct from miniaudio's own short per-channel gain smoothing.

6.4.5 Flight Loop

Final lines 174-187; original lines 176-189.

If `hasFlight` is false, the entire branch is skipped. Otherwise source position follows `ornPos` every processed frame. The target pitch is exactly $0.92f + \text{glm::clamp}(\text{ornSpeed} / 42.0f, 0.0f, 0.38f)$. It is bounded from 0.92 to 1.30 ; the upper clamp is reached at speed $42*0.38 = 15.96$, **not at speed 42**. Nonpositive speed yields 0.92 ; speed 8.4 yields 1.12 . The divisor is a gain scale, not a normalized full-speed endpoint.

The exponential mix updates `flightPitch`, then `ma_sound_set_pitch` applies it as a playback-rate/pitch factor. Changing pitch also changes the rate at which the sound's audio content is consumed; it is not time-preserving spectral pitch shifting.

`targetVol = isBoosting ? 0.40f : 0.78f` switches flight gain immediately, with no wrapper volume smoothing. The initial $0.75f$ is replaced by one of these values on the first update. Boosting lowers the ordinary flight voice so the boost voice can dominate.

If `!ma_sound_is_playing(&sndFlight)`, start it. There is **no isFlying condition** and no flight-stop branch. A loaded flight loop therefore runs in menu/end phases as long as updates pass pause/mute guards, and its location continues to follow the ornithopter. Describing this as strictly flight-phase-only would be incorrect.

6.4.6 Boost Loop

Final lines 189-195; original lines 191-197.

The `hasBoost` guard protects the sound. Position follows `ornPos`. The target is `(isFlying && isBoosting) ? 0.90f : 0.0f`; both flags must be true. `boostVolume` is smoothed with rate $8.0f$, then applied to the sound. Initialization already started this looping sound, so update does not repeatedly start/stop it and does not restart its waveform when boost begins. After release or leaving the Flying phase, the volume decays toward zero rather than instantly reaching it. Muted/paused frames freeze the application-side decay even though the loop's playback cursor continues.

6.4.7 Harvester Loop

Final lines 197-205; original lines 199-207.

If loaded, always update its position to `harvPos`. If `isFlying && attackTime < 11.0f`, start only if not already playing. Otherwise stop only if currently playing. Because `attackTime` is breach-relative, the `< 11` condition includes

all negative pre-breach times and permits playback for the first eleven seconds after breach. At exactly 11.0f, it takes the stop branch. A stop does not seek to frame zero; restarting generally resumes the source rather than rewinding unless it was at the end. The initial gain remains 0.75f because update never changes it.

6.4.8 Worm Rumble and Two Different Distances

Final lines 207-218; original lines 209-220.

If loaded, update position to wormPos. `isFlying && attackTime < 16.0f` enables the loop, again including all pre-breach times. In this branch:

```
t = clamp(wormDist / 200.0, 0.0, 1.0)
proximityBoost = mix(1.2, 0.8, t) = 1.2 - 0.4*t
```

The gain is 1.2 for distance zero or less, 1.0 at distance 100, and 0.8 at distance 200 or more. Despite its name, this value is not restricted below unity. It replaces the initial 0.9f sound gain. This gameplay modulation uses `wormGap()`; the spatializer separately applies source-to-**camera-listener** attenuation from the source's 3D position. Both factors contribute to the final signal.

Start only when needed; if the phase/time predicate fails, stop only when playing. At `attackTime == 16.0f`, stop. No local fade is requested in the stop branch and no new position is assigned for an absent cue.

6.4.9 Breach One-Shot

Final lines 220-228; original lines 222-230.

The loaded-sound branch contains `attackTime >= 0.0f && attackTime < 2.5f && !breachTriggered`. Zero is inclusive; 2.5 is exclusive. Once eligible, set `breachTriggered = true`, set position to the worm's **current trigger-time** position, seek to PCM frame 0, and start. Position is not updated again after the event, so a moving worm does not drag an already-triggered roar through space.

The latch is set before the ignored seek/start result codes. A failed start still consumes the once-per-mission event in this wrapper. The predicate does not include `isFlying`; time and latch determine eligibility if the engine update is active. If frames skip the entire 2.5-second window, no catch-up branch exists. `resetMission` re-arms it.

6.4.10 Winch/Pickup One-Shot

Final lines 230-238; original lines 232-240.

Trigger when `aboardCount > lastAboard` or `(pickupProgress > 0.08f && lastPickup <= 0.08f)`. The first condition detects any positive onboard-count change, not one sound per person. The second detects an upward threshold crossing from below-or-equal to strictly above 0.08. Remaining above the threshold produces no new threshold event. Falling below it and later crossing again can trigger another. A simultaneous count increase and threshold crossing still runs the body only once.

The body sets the source to `ornPos`, requests seek frame zero, and starts. This cue was initialized with `loop = false`. The source comment saying "Trigger or loop while picking up" is not an implementation of continuous looping. Long pickups do not continuously retrigger unless a new edge appears. Retriggering while the single sound is playing schedules a seek on the existing voice rather than mixing a second voice.

6.4.11 Safe Delivery One-Shot

Final lines 240-247; original lines 242-249.

If `hasRescueSafe` and `rescuedCount > lastRescued`, locate the cue at `basePos`, seek to zero, and start. A batch delivery with multiple rescued people emits one trigger for that processed frame. Equal or smaller totals do not trigger. The cue is spatialized at the base, not played as an unconditional nonspatial UI sound, so camera distance can make confirmation quiet. The safe-delivery branch has no separate phase restriction.

6.4.12 Periodic Crew Help

Final lines 249-262; original lines 251-264.

Proceed only if `hasCrewHelp && isFlying`. Subtract `dt` from `crewHelpTimer`. When `crewHelpTimer <= 0.0f`, check the **strict** interval `nearestCrewDist > 0.0f && nearestCrewDist < 75.0f`. Exactly zero and exactly 75 are excluded. An eligible crew member triggers position assignment, seek to zero, and start, then:

```
crewHelpTimer = 5.5f + (rand() % 30) * 0.1f
```

`rand() % 30` gives an integer from 0 through 29. The timer is therefore one of 30 nominal values 5.5, 5.6, ..., 8.4 seconds, not a continuous uniform float and not a range ending at 8.5. Modulo reduction can have small distribution bias; this code does not create a dedicated random generator or seed it locally. It consumes the program's shared C random sequence.

If the distance is ineligible, set the timer to 2.0f seconds and retry later. A large `dt` still produces at most one call/check because there is no catch-up while-loop. Negative overshoot is discarded when resetting the timer. No decrement occurs outside Flying, during pause/mute, or when the sound is absent. The first normal mission call is eligible after approximately three processed seconds, provided a crew member is within the strict distance interval. The selected source position is captured only at trigger time.

6.4.13 End-of-Frame State

Final lines 264-268; original lines 266-270. After all sound branches, unconditionally assign `lastRescued = rescuedCount`, `lastAboard = aboardCount`, and `lastPickup = pickupProgress`. "Unconditionally" here means only after getting past the engine/pause/mute early returns. The snapshots advance even if the corresponding cues are absent, preventing missing assets from continually generating the same logical edge. They are not updated when a paused/muted call returns early.

6.4.14 Spatial Attenuation Math from the Actual Vendor Code

`miniaudio.h` lines 51664-51688 implement inverse, linear, and exponential distance gains. The active inverse formula is:

```
if minDistance >= maxDistance: gain = 1
otherwise:
    d = clamp(distance, minDistance, maxDistance)
    gain = minDistance / (minDistance + rolloff*(d - minDistance))
```

Default rolloff is 1; then gain simplifies to `minDistance/d`. The distance is the listener/source relative vector's 3D length, with gain limits and directional/channel processing applied by the spatializer afterward. At or below the minimum distance, inverse attenuation is unity. Above the maximum distance, the distance is clamped and attenuation stops decreasing. There is no implicit hard culling at `maxDist`.

Cue	Inverse gain at its maximum distance, with default rolloff 1
Flight and boost	$12/150 = 0.08$
Worm rumble	$30/320 = 0.09375$
Worm breach	$45/380$, approximately 0.11842
Harvester	$18/200 = 0.09$
Winch	$15/120 = 0.125$
Safe delivery	$20/140$, approximately 0.14286
Crew help	$16/85$, approximately 0.18824

The unused linear alternative is $1 - \text{rolloff} * (d - \text{min}) / (\text{max} - \text{min})$. The unused exponential alternative is $(d / \text{min})^{(-\text{rolloff})}$. All three return unity when `min >= max` to avoid invalid division. In the default spatializer

configuration, source positioning is absolute, handedness is right-handed, forward is negative Z, min/max gain are 0/1, cones are full-circle 6.283185f, Doppler and directional factors are 1, and the minimum spatialization channel gain is 0.2f. Standalone spatializer smoothing defaults to 360 frames; the engine derives its own default 8 ms smoothing duration. The wrapper overrides attenuation distances/model, not the whole spatializer configuration.

A useful schematic, not a complete implementation equation for multichannel spatialization, is `audible sample = decoded sample * cue gain * spatial/channel gain * master gain`. The engine sums voices and clips its output; rumble gain above one and multiple overlapping voices can therefore increase clipping risk. No occlusion, environmental reverb, custom filter node, underwater/subterranean propagation model, or velocity-driven Doppler is configured by Arrakis.

6.5 Mute, Mission Reset, Shutdown, and API-Lifetime Details

6.5.1 `toggleMute()`

Final lines 131-135; original lines 133-137. No parameters or return. First flip `muted = !muted`; then, if the engine is uninitialized, return while preserving the new user state. Otherwise immediately set engine gain to 0.0f when muted or `masterVolume` when unmuted. The keyboard M handler invokes this method, and the HUD reads `g_audio.muted`.

The method does not accept or examine `isPaused`. Consequently unmuting during pause can momentarily restore engine gain until the next update mutes it again. This follows from the source; it is not an intentional pause-state integration supplied by `miniaudio`.

6.5.2 `resetMission()`

Final lines 270-276; original lines 272-278. It sets `breachTriggered = false`, `crewHelpTimer = 3.0f`, `lastRescued = 0`, `lastAboard = 0`, and `lastPickup = 0.0f`. Game-level mission reset calls this routine before rebuilding mission state.

It does not need a device and is safe before initialization because it changes only wrapper scalars. It does **not** reset `boostVolume`, `flightPitch`, `muted`, `masterVolume`, any `has*` flag, sound position, playback cursor, or playing state. Existing one-shots can continue into a restarted mission; boost/pitch smoothing history can carry across resets. The method re-arms events, not the whole audio engine.

6.5.3 `shutdown()`

Final lines 278-290; original lines 280-292. If uninitialized, return. Otherwise uninitialize every successfully created sound in this exact order: flight, boost, rumble, breach, winch, safe delivery, harvester, crew help. Then call `ma_engine_uninit(&engine)` and set `initialized = false`.

Destroying sounds first keeps their engine/resource manager alive during sound teardown. `ma_sound_uninit` detaches the sound's engine node before freeing caches and owned resource-manager data sources. `ma_engine_uninit` stops/uninitializes the owned device before tearing down the graph so the device's callback cannot read freed nodes; it then cleans up owned resources and listener state. The outer initialized guard makes a second wrapper shutdown a no-op even though the `has*` flags are not cleared.

There is no custom destructor or RAII owner in `ArrakisAudio`; normal application exit explicitly calls `g_audio.shutdown()`. Failure paths that terminate before this call must be considered separately. A future owner should not rely on aggregate destruction of `ma_engine` to free vendor allocations.

6.5.4 Exact Vendor Calls Used by the Wrapper

API	Inputs in Arrakis	What actually happens
ma_engine_config_init	None	Produces logical defaults; does not create a device. Definition at vendor line 77455.
ma_engine_init	Config pointer, stable engine address	Negotiates/creates device, graph, listeners, and internal resource manager; can fail with a ma_result. Definition 77521.
ma_engine_listener_set_world_up	Engine, index 0, (0, 1, 0)	Establishes listener orientation's up axis.
ma_sound_init_from_file	Engine, path, flags 0, group null, fence null, destination	Wraps sound config and creates a resource-managed data source and engine node. Definition 78567.
ma_sound_set_looping	Sound, MA_TRUE/MA_FALSE	Changes data-source loop behavior; not a call to start playback.
ma_sound_set_min_distance, ma_sound_set_max_distance, ma_sound_set_attenuation_model	Sound and configured scalar/enum	Update spatializer attenuation configuration.
ma_sound_set_volume	Sound and linear gain	Delegates to engine-node volume state. Definition 78832.
ma_engine_set_volume	Engine, zero or masterVolume	Controls endpoint/master output gain; does not pause source transport.
ma_engine_listener_set_position, ma_engine_listener_set_direction	Engine, listener 0, three components	Set listener spatial values; positions/directions use vendor synchronized vector storage.
ma_sound_set_position	Sound and three world components	Sets source spatial position; no pointer to the caller's GLM vector is retained.
ma_sound_set_pitch	Sound and flightPitch	Changes engine-node resampling/pitch ratio.
ma_sound_is_playing	Sound pointer	Queries node/playback state to avoid unnecessary starts/stops.
ma_sound_start	Sound pointer	Returns success if already playing; if at end, seeks/re-arms; sets node state started. Definition 78746.
ma_sound_stop	Sound pointer	Sets stopped node state; does not destroy or automatically rewind. Definition 78774.
ma_sound_seek_to_pcm_frame	Sound, frame 0	Schedules an atomic seek target for the mixing thread; actual seek is not performed synchronously by this wrapper call. Definition 79425.
ma_sound_uninit	Each valid sound pointer	Detaches node, releases processing cache and owned source; definition 78699.
ma_engine_uninit	Engine pointer	Stops callback access before releasing graph/device/manager/listener resources; definition 77795.

The wrapper checks engine/sound **initialization** results but ignores later start, stop, seek, and master-volume results. A gameplay event can be consumed even if the device or underlying source later fails. Documentation should distinguish intended cue dispatch from confirmed audibility.

6.6 miniaudio_impl.cpp and Compile-Time Selection

6.6.1 Both Lines of the Implementation Unit

Line 1 is `#define MINIAUDIO_IMPLEMENTATION`; line 2 is `#include "miniaudio.h"`. That macro selects the definitions below the public header region. It must be used in **one** compiled translation unit to avoid multiple external definitions. Other game headers include `miniaudio.h` without it and see declarations/types only.

The public header guard is `miniaudio_h`; the implementation has a separate `miniaudio_c` guard and is selected by either `MINIAUDIO_IMPLEMENTATION` or `MA_IMPLEMENTATION` at line 11552. Separate guards permit the common pattern of including declarations and later including an implementation in the same translation unit. Editor-analysis macros around lines 11538-11543 can enable implementation visibility for IntelliSense/Qt Creator/CDT; that is not the normal executable build's source-selection mechanism.

CMake and the inspected Visual Studio project compile the main application, GLAD C unit, and this miniaudio C++ unit. Merely retaining another .c file on disk does not compile it. Include directories make `miniaudio.h` resolvable from its organized third-party location; physical relocation by itself does not enable a codec.

6.6.2 Is stb_vorbis Compiled or Necessary?

The answer for the inspected project is **no, it was never compiled or included and has now been removed; no, it is not necessary for the eight active preferred WAV/MP3 files**. The two-line implementation unit does not include it. Neither executable source list contains it. The miniaudio Vorbis adapter begins at line 65330 under `#ifdef STB_VORBIS_INCLUDE_STB_VORBIS_H`; that macro is defined by `stb_vorbis`'s declaration section, but no project source makes those declarations visible before the miniaudio implementation.

To use this particular optional adapter, `stb_vorbis` declarations must be visible when miniaudio's implementation is compiled and `stb_vorbis` definitions must be linked exactly once. A declaration-only include using `STB_VORBIS_HEADER_ONLY`, followed by miniaudio implementation and one separately compiled `stb_vorbis` implementation, is one possible integration design. A single-translation-unit inclusion arrangement is another. These are explanations of requirements, **not changes made to the build**. Adding `stb_vorbis.c` alone to CMake without exposing its declarations to miniaudio does not activate the adapter. Defining its header guard alone without declarations is also not valid integration.

An alternate custom Vorbis decoder could satisfy Ogg support instead. Vorbis would become necessary only if the game relies on Ogg assets and chooses this codec implementation. The filename suffix .ogg denotes a container; arbitrary Ogg-contained codecs such as Opus are not decoded by a Vorbis-only decoder.

6.6.3 Compile-Switch Families and Dependencies

Build-switch documentation is at lines 547-718, platform/type detection starts at 3860, backend feature selection is at 6654-6699, and implementation selection is at 11552.

Switch family	Effects and cautions
MA_NO_WASAPI, MA_NO_DSOUND, MA_NO_WINMM, MA_NO_ALSA, MA_NO_PULSEAUDIO, MA_NO_JACK, MA_NO_COREAUDIO, MA_NO_SNDIO, MA_NO_AUDIO4, MA_NO_OSS, MA_NO_AAUDIO, MA_NO_OPENSL, MA_NO_WEBAUDIO, MA_NO_CUSTOM, MA_NO_NULL	Remove individual device backends. They do not automatically remove the engine's platform-neutral DSP.
MA_ENABLE_ONLY_SPECIFIC_BACKENDS and matching MA_ENABLE_* macros	Change backend selection to an explicit allowlist. Platform support is still required; enabling ALSA on Windows does not manufacture Linux APIs.
MA_NO_DEVICE_IO	Removes context/device playback/capture APIs; allows decode/conversion-only uses, or a no-device engine with explicit channels/sample rate. Not selected in Arrakis.

Switch family	Effects and cautions
MA_NO_THREADING	Removes thread/mutex/semaphore/event support. Device I/O must also be disabled; worker behavior and resource-manager configuration change.
MA_NO_DECODING, MA_NO_ENCODING	Remove decoder or encoder API sections. The resource manager requires decoding; disabling decoding forces the related dependency change.
MA_NO_WAV, MA_NO_FLAC, MA_NO_MP3; optional MA_NO_VORBIS	Remove individual built-in/adapted codecs. WAV also supplies the built-in encoder. None of these are defined in the two-line implementation unit.
MA_NO_RESOURCE_MANAGER	Removes resource-managed file loading and file-based engine helpers, including the exact <code>ma_sound_init_from_file</code> API the game needs. External data sources remain possible.
MA_NO_NODE_GRAPH, MA_NO_ENGINE	Remove graph or high-level engine APIs. The engine depends on the graph; Arrakis needs both.
MA_NO_GENERATION	Removes waveform/noise generator APIs; the game does not use them.
MA_NO_SSE2, MA_NO_AVX2, MA_NO_NEON	Remove CPU-specific optimization paths while retaining scalar implementations where available.
MA_NO_RUNTIME_LINKING	Replaces dynamic system-library loading requirements with directly linked backend symbols; may require additional linker configuration.
MA_USE_STDINT, MA_API, allocation/assert/log customization macros	Control sized types, symbol decoration, allocation hooks, diagnostics, and embedding policy rather than cue semantics.
MA_COINIT_VALUE, MA_FORCE_UWP	Windows COM initialization and Windows-app backend behavior. Default COM model is multithreaded.
MA_ON_THREAD_ENTRY, MA_ON_THREAD_EXIT, MA_THREAD_DEFAULT_STACK_SIZE	Hooks/stack size for internally created threads; must not be confused with gameplay frame callbacks.
MA_ENABLE_AUDIO_WORKLETS	Emscripten worklet path; requires matching toolchain options such as <code>-SAUDIO_WORKLET=1</code> <code>-sWASM_WORKERS=1</code> <code>-sASYNCIFY</code> . Not the Windows path.

Declarations, implementation, and consumers must agree on configuration macros and struct layouts. miniaudio explicitly does not guarantee ABI compatibility even across patch versions. The safest use here is the supplied header and implementation compiled together, not arbitrary interchange with another binary miniaudio version.

6.7 miniaudio: Complete Coverage Map and Functional Architecture

6.7.1 Complete Contiguous Source Map

All numbers in this subsection refer to the inspected 95,864-line `miniaudio.h`, unchanged by relocation. Boundaries include separator comments/blank lines so there are no uncovered source regions. A broad bin can contain shared helpers belonging to the adjacent family; the declaration and definition names provide the exact semantic entry points.

Lines	Functional contents
1-3737	Version/provenance; complete in-header manual, examples, build switches, low/high-level APIs, resource manager, graph, decoding/encoding, conversion, filters, generation, buffering, backends, and optimization notes
3738-4515	Public guard/linkage, fixed-width/platform types, result/error enums, formats/channels, allocation callbacks, atomic/thread type declarations, version APIs

Lines	Functional contents
4516-4590	Logging callback/configuration APIs
4591-5003	Biquad, low-pass, high-pass, band-pass, notch, peaking EQ, low/high shelf declarations
5004-5317	Delay, gainer, stereo panner, fader, vector/spatializer/listener declarations
5318-5830	Linear/general resampling, channel conversion, data conversion, format conversion, channel-map helpers
5831-6111	Data-source base/vtable APIs; borrowed/owned/paged audio buffers; ring-buffer declarations
6112-6593	Results/allocations/miscellaneous helpers, spinlocks and OS synchronization, fences, notifications, slot allocation, job queue
6594-9751	Backend selection, context/device IDs/configs/callbacks/native structs; enumeration, lifecycle, volume, buffer-size and device helper APIs
9752-9865	PCM copying, silencing, clipping, volume/mix/interleave utilities
9866-9944	Virtual filesystem and file-I/O abstraction declarations
9945-10110	Generic decoder and custom decoding-backend APIs
10111-10169	Encoder configuration/callback/API declarations
10170-10296	Waveform, pulsewave, and white/pink/brownian noise declarations
10297-10614	Resource-manager configuration, flags, buffer/stream/source objects, registration, notifications, job processing
10615-11107	Node graph, input/output buses, node/vtable/state flags, endpoint/source/splitter and filter/delay node APIs
11108-11535	Engine/engine-node/sound/group configuration, listener/control/scheduling APIs and public guard closure
11536-13569	Implementation gate/includes; architecture/SIMD/compiler detection; platform linkage, memory/string and portability groundwork
13570-18578	Logging definitions; internal math/random/vector/string/platform helpers, atomics, thread creation and synchronization, fences/notifications
18579-19470	Slot allocator and bounded job queue implementation
19471-20933	Common device-I/O definitions, backend platform types/constants, conversions, descriptors, and shared setup
20934-21707	Null backend: virtual timing/buffering device without physical output
21708-25216	WASAPI backend, COM/interface shims, endpoint enumeration, format negotiation, event/client processing, notifications/routing
25217-27001	DirectSound backend and playback/capture/notification interface/buffer management
27002-28101	WinMM waveform input/output backend
28102-30262	ALSA PCM backend, including enabled body through 30254 and boundary/shared setup

Lines	Functional contents
30263-32799	PulseAudio backend and server/mainloop/stream interactions
32800-33476	JACK client, port, sample-rate and callback backend
33477-36716	Core Audio/AudioUnit backend and Apple device/routing handling
36717-37563	sndio backend
37564-38460	BSD audio(4) backend
38461-39094	OSS backend
39095-40230	AAudio backend, error/reroute jobs, and absent-backend no-op job glue
40231-41494	OpenSL ES backend and Android object/queue/channel mapping
41495-42450	Web Audio JavaScript/Emscripten bridges and optional worklet processing
42451-44574	Shared context/backend dispatch, enumeration, device lifecycle, device jobs, state transitions, period/buffer selection
44575-45089	Buffer-duration calculations; PCM copy/silence/clip/volume/mix helpers
45090-47163	Sample-format conversion, scalar/SIMD conversion paths, normalization/dithering/interleaving support
47164-50374	Biquad and all filter-family implementations
50375-53026	Delay, gainer, panner, fader, listener/spatializer, attenuation, cone, Doppler and directional gains
53027-54276	Linear and generic/custom-vtable resampling implementations
54277-55901	Channel conversion, mono expansion, rearrangement, weighted mixing
55902-57072	Composite data converter and frame-count/latency processing
57073-58096	Channel maps and one-shot conversion helper implementations
58097-58922	Byte/PCM ring buffer operations and duplex buffering support
58923-60903	Result descriptions, allocation wrappers, sample-size helpers, data-source operations, borrowed/owned/paged audio-buffer implementations
60904-61933	VFS callback dispatch and default filesystem implementation; generated-decoder-header preamble
61934-62368	Embedded dr_wav 0.14.5 declarations, structs, metadata, read/write/seek/format conversion APIs
62369-62662	Embedded dr_flac 0.13.3 declarations, bitstream/metadata/seek/read APIs
62663-62839	Embedded dr_mp3 0.7.3 declarations, frame/decoder state, read/seek/metadata APIs
62840-65329	Generic decoding groundwork and WAV/FLAC/MP3 data-source/backend adapters
65330-66159	Optional stb_vorbis adapter, excluded unless stb_vorbis declarations are visible

Lines	Functional contents
66160-67830	Generic decoder initialization/probing, callback/file/memory paths, output conversion, reading/seeking/length/cursor helpers
67831-68147	Built-in WAV encoder adapter, encoder initialization/writing/teardown
68148-69308	Waveform/pulsewave and noise generator implementations
69309-73426	Resource manager: path/hash registry, cached buffers, streamed pages, job dispatch, synchronization, source operations
73427-76536	Node graph: graph traversal/mixing, attachment lists, state/scheduling, source/splitter/filter/delay nodes
76537-79893	Engine, listeners, engine-node processing, sound/group loading/control/seeking/fades and inlined sounds
79894-79907	Embedded codec-implementation preamble and warning/integration setup
79908-84837	Embedded dr_wav implementation
84838-92696	Embedded dr_flac implementation
92697-95804	Embedded dr_mp3/minimp3-derived implementation
95805-95864	Warning-state restoration, implementation guards, public-domain/MIT No Attribution license alternatives

6.7.2 Object Model, Results, Memory, and PCM Units

The main recurring pattern is `*_config_init`, `*_init` or `*_init_preallocated`, `*_process_pcm_frames/read/control` calls, and `*_uninit`. Configs are temporary descriptions; initialized objects are long-lived, noncopyable-in-practice structures containing caches, locks, pointers, and ownership bits. Some components expose `*_get_heap_size` plus preallocated initialization to let the application provide one suitably aligned backing block; ordinary initialization allocates using `ma_allocation_callbacks`.

`ma_result` is a signed result enum: `MA_SUCCESS = 0`, with negative error/status values. General argument/memory/I/O errors, no-data/at-end states, unsupported-format errors, device/backend failures, and cancellation are distinct. Device errors include `MA_NO_BACKEND = -203`, `MA_BACKEND_NOT_ENABLED = -208`, and initialization/open/start/stop backend errors `-400` through `-403`. `ma_result_description` at line 58926 translates known result values to readable text; Arrakis prints numeric initialization results instead. Success from sound start means the request/state transition was accepted, not that the operating-system speakers audibly emitted the cue.

`ma_malloc`, `ma_realloc`, `ma_free`, aligned allocation, and copied allocation callbacks keep allocation/free policy paired. Borrowed data must outlive its reader; owned data is released by the corresponding `uninit`. Resource-manager buffers can be shared/refcounted, while independent decoder cursors belong to their consumers. Caller-provided memory and an external manager/device must not be freed as if owned; ownership flags decide teardown.

A PCM **frame** contains one sample for each channel. For interleaved audio, bytes required are `frameCount * channels * bytesPerSample`; stereo f32 uses 8 bytes per frame. A stereo frame count of 480 is 10 ms at 48 kHz, not 960 ms or 960 frames. f32 is conventionally `[-1, 1]`; s16 is `[-32768, 32767]`; packed s24 uses three bytes; s32 uses four; unsigned u8 silence is **128**, while signed/float silence is zero. The source's `ma_silence_pcm_frames` explicitly handles that distinction at lines 44606-44616.

Conversion and decode functions often return both a result and an actual frame count, or update consumed/produced count pointers. The caller must respect partial output and buffer capacities instead of assuming a requested count was produced. Frame-index APIs can use 64-bit types even when an underlying optional decoder has a narrower seek limitation.

6.7.3 Logs, Atomics, Threads, Notifications, and Jobs

Logging (`ma_log_*`) stores registered callbacks, severity, user data, and synchronization around callback registration/posting. Version/math/string/vector and platform helpers underpin all later subsystems; they are not game logic. SIMD dispatch selects suitable implementations after compiler/architecture detection rather than assuming every CPU supports all enabled instruction sets.

Atomic helpers implement integer/pointer/float access and synchronized vector snapshots using supported compiler intrinsics or fallback locking. They let the game publish spatial/control state while the mixer consumes it. This does **not** imply that arbitrary direct edits to transparent struct members are safe, or that every public function is callback-safe.

`ma_thread_*`, `ma_mutex_*`, `ma_event_*`, `ma_semaphore_*`, and spinlocks abstract Windows and pthread/platform primitives. Events are wakeup mechanisms; a fence tracks outstanding work and permits waiting until completion; asynchronous notifications can use callbacks, event/fence adapters, or their combinations.

`ma_sound_seek_to_pcm_frame` illustrates deferred ownership: the game thread atomically publishes a target; the thread reading audio performs the actual decoder seek, avoiding concurrent decoder mutation.

The slot allocator reserves a fixed collection of job storage slots with generation/counter bookkeeping, reducing allocation churn and avoiding reuse confusion. The bounded job queue posts and retrieves typed jobs, optionally waits or reports `MA_NO_DATA_AVAILABLE`, and uses quit/cancellation semantics. Jobs include resource load/free/page/seek work and AAudio rerouting; a queue-capacity failure is different from decoding failure. The resource manager defaults to **one** managed job thread, as seen at line 69977, not one thread per sound.

The device's realtime callback must produce exactly the requested frame region without blocking filesystem work, expensive unbounded allocation, or waiting on device lifecycle operations. The manual explicitly forbids device `init/uninit/start/stop` from within its own callback because that can deadlock. Arrakis performs these lifecycle actions from application setup/shutdown, not from a custom device callback.

6.7.4 Device/Context Abstraction and Backend Families

`ma_context` selects a usable backend, holds global backend state/function tables, manages logs/allocation callbacks, and enumerates playback/capture devices. `ma_device_id` is a backend-specific identifier; display names are not a universal persistent device handle. `ma_device_config` expresses playback/capture format, channels/maps, rate, share mode, periods, callbacks, user data, and backend options. `ma_device` owns negotiated native state, conversion paths, intermediate buffers, synchronization, and start/stop state.

Device types are playback, capture, duplex, and supported loopback modes. Playback callbacks write output; capture callbacks read input; duplex can do both. Native device format can differ from callback format, so conversion occurs at the boundary. Period sizes, native sample rates, backend buffering, and callbacks determine actual latency; the game's graphics dt does not drive sample delivery.

Default backend priority from the supplied manual is WASAPI, DirectSound, WinMM, Core Audio, sndio, audio(4), OSS, PulseAudio, ALSA, JACK, AAudio, OpenSL ES, Web Audio, Custom, Null. Unavailable/uncompiled backends are skipped; initialization can fall through until a usable backend is found. A Windows compilation excludes Linux/BSD/Apple/Android implementations through feature guards even though their source remains in the header.

Backend	Native mechanism, threading/buffering, and limits
WASAPI; 21708-25216	Windows COM MMDevice/AudioClient interfaces, endpoint discovery, shared/exclusive format negotiation, event/client buffering, render/capture services, loopback, endpoint notifications and rerouting. COM startup and some commands need carefully chosen threads. Low-latency shared mode has sample-rate/autoconversion caveats; UWP has default-device and capability restrictions.
DirectSound; 25217-27001	Windows playback/capture buffer interfaces and notifications. Ring/circular-buffer positions and notifications drive chunk transfer. Interface release and DLL ownership are separate from sound data ownership. This is a fallback backend, not OpenGL's Direct State Access.

Backend	Native mechanism, threading/buffering, and limits
WinMM; 27002-28101	Older Windows waveOut/waveIn style devices and queued waveform headers/buffers. Completion/requeue logic feeds output or gathers input; format support and latency differ from WASAPI.
ALSA; 28102-30262	Linux PCM devices, hardware/software parameter negotiation, read/write or supported mapped transfer, polling/wakeup and recovery for underruns/overruns. Dynamic libasound resolution avoids requiring its development headers in the normal embedded build.
PulseAudio; 30263-32799	Server-based playback/capture streams, context/mainloop synchronization, server/device enumeration and stream buffering/latency requests. Server policy can route devices automatically; the game does not issue PulseAudio calls directly.
JACK; 32800-33476	JACK client/ports and server realtime process callback. Server rate/channel/period constraints and port connection define operation; callback processing must fit realtime deadlines.
Core Audio; 33477-36716	Apple device/AudioUnit machinery, render/capture callbacks, stream properties and route changes. macOS/iOS platform branches have different device/default-route behavior and Apple linkage paths.
sndio; 36717-37563	OpenBSD libsndio handle/options and PCM transfer with polling/drain/volume support as provided by the backend. Normally enabled on OpenBSD only.
audio(4); 37564-38460	NetBSD/OpenBSD device files and audio ioctl/configuration structures with read/write transfer. On OpenBSD, an active sndiod can affect availability.
OSS; 38461-39094	FreeBSD/OSS-style device file and ioctl format/rate/channel negotiation, read/write/polling; platform-specific capability/device constraints.
AAudio; 39095-40230	Android stream builder/stream APIs, realtime data/error callbacks, usage/content/input presets, disconnect handling and reroute jobs. Android 8+; native enumeration is limited to default devices unless the app supplies Java-discovered IDs.
OpenSL ES; 40231-41494	Android engine/mix/player/recorder objects, PCM channel-mask translation and buffer-queue callbacks. Single application-level engine/context constraints, queued buffer lifetime and API 16+ requirements matter.
Web Audio; 41495-42450	Emscripten JavaScript audio context/device bridges, script processing and optional AudioWorklet path. Browser user-gesture/autoplay restrictions and no-pthread builds change startup/job processing.
Custom	Application-supplied backend callbacks/vtable enter the common context/device dispatch; there is no separate magic hardware driver implementation to describe. Correct lifecycle, enumeration and data transfer are the application's responsibility.
Null; 20934-21707	Software clock/buffer/callback device without physical playback. Useful for testing or fallback; a successfully initialized null endpoint does not prove audible output.

Backend structs and shims include ABI-compatible native declarations/function pointers, library opening/closing, native enumeration/configuration, format/rate conversion, device init/uninit/start/stop, processing or callback entry, and backend-specific error translation. The common dispatch at lines 42451-44574 wires these into one public API. Unsupported branches return result codes rather than selecting an unrelated graphics API. Runtime linking is platform-specific; MA_NO_RUNTIME_LINKING changes linker obligations. On Linux the supplied manual calls for `-ldl`

- lpthread - lm, possibly - latomic for 32-bit ARM; the Windows-specific project link configuration should not be described as already implementing every portability requirement.

6.7.5 PCM Utilities and DSP Filter Families

Utilities copy/silence PCM, compute offsets, clip values, apply gains, mix streams and interleave/deinterleave channel storage. They distinguish frames from samples and signed from unsigned silence. Format converters cover u8/s16/s24/s32/f32 with scalar/SIMD paths, scaling, clipping and requested dithering behavior. A conversion's direction determines destination capacity and precision loss; changing byte representation is not resampling.

The biquad family stores coefficients plus per-channel delay/register state. Its mathematical prototype is $y[n] = (b_0 \cdot x[n] + b_1 \cdot x[n-1] + b_2 \cdot x[n-2] - a_1 \cdot y[n-1] - a_2 \cdot y[n-2]) / a_0$; implementations normalize coefficients and choose supported processing formats. `reinit` can replace configuration while retaining history, unlike tearing down/reinitializing the object. Separate channels need separate state.

DSP family	Declaration lines; definition entry	Explanation
<code>ma_biquad_*</code>	4593-4642; config at 47166	General second-order filter with caller coefficients, heap/preallocated state and in-place/buffer processing.
<code>ma_lpf1_*</code> , <code>ma_lpf2_*</code> , <code>ma_lpf_*</code>	4645-4731; 47487 onward	First/second/higher-order low-pass filters, cutoff and sample rate; cascaded sections for higher-order Butterworth behavior. Removes high frequencies and supplies resampler antialias smoothing.
<code>ma_hpf1_*</code> , <code>ma_hpf2_*</code> , <code>ma_hpf_*</code>	4734-4817; 48376 onward	High-pass counterparts, retaining high frequencies and rejecting low/DC components.
<code>ma_bpf2_*</code> , <code>ma_bpf_*</code>	4820-4879; 49200 onward	Band-pass sections controlled by center/cutoff frequency and Q; higher-order family cascades sections.
<code>ma_notch2_*</code>	4882-4909; 49686	Rejects a narrow band while retaining frequencies outside it.
<code>ma_peak2_*</code>	4912-4940; 49859	Peaking equalization with frequency/Q/gain in dB; boosts or cuts around a center.
<code>ma_loshelf2_*</code>	4943-4971; 50034	Low-frequency shelf, gain in dB and slope.
<code>ma_hishelf2_*</code>	4974-5003; 50207	High-frequency shelf counterpart.
<code>ma_delay_*</code>	5005-5039; 50379	Circular delayed sample history, delay frame count and decay/dry-wet controls; stateful echo, not decoder seeking.
<code>ma_gainer_*</code>	5040-5074; 50533	Per-channel gains and gradual transition over configured frames; smooths control changes.
<code>ma_panner_*</code>	5075-5109; 51078	Stereo balance/pan modes modify left/right gains; not full 3D geometry.
<code>ma_fader_*</code>	5110-5137; 51286	Time/frame-position-dependent fades and gain endpoints; seconds/milliseconds must be converted using sample rate.
<code>ma_spatializer_listener_*</code> , <code>ma_spatializer_*</code>	5138-5317; spatial config at 52051	Source/listener coordinate transform, distance/cone/directional attenuation, speaker-channel weighting, gain interpolation, and Doppler ratio.

Arrakis invokes gain, pitch and spatialization through the engine; it does not construct custom low/high-pass, shelf, notch, delay or noise objects. Their vendor code is still included by the unspecialized implementation configuration, though unused functions may be removed by link-time/dead-code optimization depending on the build.

6.7.6 Resampling, Channel Conversion, and Composite Conversion

`ma_linear_resampler_*` config begins at 53032. It maintains fractional source position, previous samples/filter state and an input/output rate relationship. Linear interpolation estimates between adjacent samples; low-pass filtering limits aliasing when rates change. Required-input/expected-output/latency helpers describe how much input is needed and how delay affects frames. Dynamic rate/ratio setters support pitch or device-rate changes without rebuilding every object.

`ma_resampler_*` dispatches either the built-in linear resampler or a custom resampler vtable, handling init/heap/process/reset/rate/count/latency operations. An external implementation must obey frame-count and lifetime contracts. Pitch is usually expressed by modifying the consumption ratio, which changes duration as well as frequency. The default engine pitch-resampling config uses f32 linear resampling with low-pass order 0 at lines 77464-77465; the vendor comment explicitly cites instability concerns for some pitch-filter cases. Do not infer a separate studio-quality time-stretch algorithm.

`ma_channel_converter_*` creates mono expansion, positional channel mapping, reordering and weighted mixing. It can use passthrough/copy paths when layouts match; adding or removing channels is a different operation from changing sample rate. Channel maps encode speaker positions, not merely ordinal indexes; surround-to-stereo and mono-to-multichannel policies affect spatial perception.

`ma_data_converter_*` composes format conversion, channel conversion and resampling, chooses efficient processing order/caches, calculates heap requirements, and updates consumed/produced frame counts. Unknown/default fields are resolved before processing. PCM format changes can lose precision; resampling adds state and latency; channel conversion may mix information. Single-shot `ma_convert_*` helpers build or drive these operations for one buffer, while long-running converters retain state across blocks.

6.7.7 Data Sources, Buffers, Rings, and Filesystem

`ma_data_source` is a common read/seek/format/cursor/length/loop interface implemented through a vtable and base state. It also supports source ranges, loop points and chaining. The base operations enforce ranges and looping around underlying readers. Not all sources implement seeking or reliable length; callers must inspect results rather than assuming a finite file-backed stream.

`ma_audio_buffer_ref` borrows a PCM array and maintains a cursor without owning the array. `ma_audio_buffer` can allocate/copy/own storage according to its config, and its uninit releases owned storage through matching callbacks. Paged buffers link PCM pages and let producers expose growing decoded data; page ownership and lifetime must not race readers. Data-source initialization entry is 59138, borrowed-buffer init 60044, owned-buffer init 60361, paged-buffer init 60733.

`ma_rb` is a byte ring; `ma_pcm_rb` adds format/channel/frame knowledge. Acquire/commit read and write APIs expose contiguous regions, handle wraparound, and advance cursors only on commit. Ring buffers are documented for **one consumer and one producer**, not arbitrary multi-reader/multi-writer access. Available read/write counts prevent overrunning unread data or reading unwritten data. Duplex helpers buffer between capture/playback clock domains; differing clocks can drift even when nominal sample rates match.

The VFS is a callback table for open/close/read/write/seek/tell/info. Default VFS uses OS/CRT filesystem operations with narrow/wide path variants and 64-bit-position support where available. Decoders and resource manager can use a custom archive/memory/package filesystem without hardcoding game paths. Arrakis does not supply one: it performs a standard `ifstream` pre-probe and then lets miniaudio's default VFS open the selected path. That double-open pattern allows a file to change/disappear between lookup and decode.

6.7.8 Decoders, Probing, Adapters, and Encoder

`ma_decoder_config` describes requested output format/channels/rate, maps/mixing/resampling, allocation callbacks and optional custom backend vtables. `ma_decoder` owns one selected backend plus conversion/cursor/cache state. Its callback, VFS-file, wide-file and memory initializers attempt supported backends, establish native audio properties and configure output conversion. Built-in and custom backend attempts can fail and be cleaned up before the next attempt; an encoding hint/extension can guide selection but existence or suffix is not authoritative content validation.

The WAV adapter, FLAC adapter, MP3 adapter and optional Vorbis adapter expose codec-specific states as `ma_data_sources`. Their vtables translate read/seek/get-format/get-cursor/get-length into codec functions and normalize result reporting. Definitions and declarations inside the implementation region are internal integration scaffolding, not evidence the wrapper calls those functions directly.

`ma_decoder_read_pcm_frames` reads native decoded PCM and converts it to configured output while honoring partial counts/EOF. Seek operations reset or reposition dependent state; cursor and length are in PCM frames, not encoded bytes. Memory decoders borrow encoded memory for their decoder lifetime unless the surrounding manager owns a loaded copy. File decoders must close file state during teardown. Whole-file decode helpers allocate output PCM that the caller must free with the corresponding allocator.

The optional `ma_stbvorbis` state stores a base data source, read/seek/tell callbacks and user pointer, allocation callbacks, f32 format, channels/rate, 64-bit reported cursor, the stb decoder pointer, push/pull mode and push-buffer/cache state. `MA_VORBIS_DATA_CHUNK_SIZE` is **4096 bytes**. Callback mode uses pushdata because stb_vorbis's pull API lacks generic read callbacks; file/memory modes can use stb's native pull APIs. Push mode accumulates encoded bytes, tracks consumed bytes and remaining planar samples, then copies/interleaves output. Buffer growth and stb's `int` length APIs impose checked size limits. Push seeking can rebuild/redecode from the beginning because flush-and-arbitrary-seek is not robust enough for this adapter. Push-mode length is reported as zero where reliable length cannot be obtained; native pull mode can query stream length. Adapter allocation callbacks do not automatically control stb_vorbis's own malloc/alloca use.

The encoder family supports the built-in WAV encoder, not MP3/Vorbis/FLAC encoding merely because those decoders exist. It initializes a write/seek callback or file target with an explicit encoding format and PCM format/rate/channels, writes PCM frames, and finalizes/patches container bookkeeping during uninit where supported. Sequential writers need total-size knowledge when seeking is unavailable. Arrakis does not record or encode audio.

6.7.9 Embedded WAV Implementation: All Subfamilies

The embedded copy is `dr_wav 0.14.5`, renamed with `ma_dr_wav_*` symbols to coexist with independent `dr_wav` users. Declarations occupy 61934-62368; implementation occupies 79908-84837. This is actual codec/container code included in `miniaudio`, not a reference to a separately installed DLL.

Implementation lines	Functional explanation
79908-81736	Version/platform/memory/endian helpers; RIFF/WAVE, Wave64 and RF64 container identification and chunk iteration; fmt/data discovery; padding/size accounting; format/subformat validation; metadata parsing/allocation and setup/read callbacks. Unknown chunks are skipped subject to lengths; truncated/invalid headers fail instead of becoming arbitrary PCM.
81737-82850	Public callback/memory/file initialization, sequential and seekable writer setup, metadata-aware writer variants, file wrapper callbacks, uninitialization/finalization, raw reads/writes, cursor/length/seek and common PCM transfer. Ownership flags distinguish library-opened files from borrowed callback data.
82851-83967	Native PCM reads and endian variants, format-specific s16 and f32 conversion helpers, A-law/mu-law expansion, Microsoft ADPCM and IMA/DVI ADPCM block decoding with predictor/history and cached decoded frames. Encoded bytes and PCM frames have different ratios for compressed WAV.

Implementation lines	Functional explanation
83968-84837	f32/s32 normalized read variants, remaining scalar conversion families, callback/file/memory whole-file decoding helpers, allocation/free/error handling and embedded implementation closure. Whole-file helpers allocate a buffer, repeatedly decode and return actual frame count; they do not leak ownership to the engine without an explicit handoff.

RIFF chunk sizes/padding, extensible format tags and channel/sample metadata are validated before data transfer. Supported WAV encodings include integer PCM, IEEE float and the listed telephony/ADPCM formats; .wav is a container, not a guarantee of uncompressed 16-bit PCM. Writes use supported uncompressed/container formats and header bookkeeping; having an ADPCM decoder does not imply the library writes every compressed WAV format. The game uses ordinary WAV reads for harvester, winch, safe and crew cues, without directly invoking metadata-aware authoring APIs.

6.7.10 Embedded FLAC Implementation: All Subfamilies

The embedded copy is `dr_flac 0.13.3`, namespaced as `ma_dr_flac_*`. It is a lossless decoder; no FLAC assets are selected by the wrapper's candidate lists.

Implementation lines	Functional explanation
84838-86342	Portability/SIMD/byte-order helpers, allocation callbacks, CRC tables/checks, buffered bitstream reads, signed/unsigned extraction and FLAC frame/header number decoding. Efficient cache/bit reads are bounded by available data and the decoded field width.
86343-87624	Rice-coded residual reading; reference/scalar/SSE4.1/NEON predictor paths; escape/unencoded residual partitions and residual seeking. Unary quotient plus Rice remainder reconstruct signed residuals, which are added to a prediction rather than treated as finished audio.
87625-88555	Constant/verbatim/fixed-order/LPC subframe decoding, warm-up samples, coefficients and shift, wasted-bit restoration, frame/subframe headers, channel decorrelation, frame validation, skipping and seek-forward helpers. Fixed predictors and LPC reconstruct original integer samples losslessly.
88556-90162	Metadata block parsing, STREAMINFO, seektable and optional metadata callbacks, decoder allocation/init preparation, native FLAC/Ogg mapping infrastructure and callback/memory/file setup groundwork. Container metadata is distinct from PCM.
90163-92265	Public open/close variants, file/memory adapters, seek strategies and output-read paths, conversion/interleaving to s32/s16/f32, optimized channel decorrelation and buffering. Seek tables accelerate location but absent tables do not necessarily make decoding impossible.
92266-92696	Public f32 frame-reading entry, remaining whole-file/memory convenience and cleanup/implementation closure. Allocated output and decoder-object ownership are documented separately.

For predictive subframes, conceptual reconstruction is `sample[n] = prediction(previous samples, coefficients) + residual[n]`, with shifts and bit widths dictated by the stream. Rice residual decoding maps a quotient/remainder code back to a signed integer. Stereo channel assignments include independent, left-side, right-side and mid-side; decoding reverses the selected decorrelation. CRC and validated bounds are part of handling malformed data but do not establish that every vendor branch was audited here. FLAC's Ogg-container facilities do not make it a Vorbis decoder.

6.7.11 Embedded MP3 Implementation: All Subfamilies

The embedded copy is `dr_mp3 0.7.3`, namespaced as `ma_dr_mp3_*`; low-level decode machinery derives from `minimp3`. This decoder is directly relevant to flight, boost and worm cues.

Implementation lines	Functional explanation
92697-94591	Portability/SIMD setup, callback/file I/O, seek/metadata helper groundwork and minimp3-derived core: MPEG frame synchronization/header interpretation, bit readers, Layer I/II scale-factor/dequantization processing, Layer III side information/scalefactors/Huffman decode, bit reservoir, stereo processing, requantization, short-block reorder, antialiasing, inverse transforms and polyphase synthesis. Tables encode codec constants; SIMD accelerates equivalent PCM reconstruction.
94592-94979	Higher-level next-frame decoding for callback and memory inputs, encoded-buffer refill/compaction, metadata/frame-start and stream setup, native format properties and decoded-frame cache management. A frame can need reservoir bytes retained from earlier compressed frames.
94980-95264	Public callback/file/memory init variants, metadata callbacks, teardown and common read preparation; ownership/allocation errors and first-frame initialization are handled here.
95265-95804	f32/s16 frame reads, PCM cursor/length, seeking and seek-point tables, frame/PCM count helpers, whole-file convenience decoding, free functions, and implementation closure. Seeking generally locates an encoded frame then decodes/discards as necessary to reach a requested PCM position.

Constants in declarations include maximum **1152 PCM frames per MP3 frame**, maximum **2304 samples** for two channels, maximum **511 reservoir bytes**, and **2304** free-format frame-size constant. These are codec-buffer limits, not the game's audio-callback frame size. Layer III uses a compressed bit reservoir, so a sound cannot always begin decoding correctly from an arbitrary encoded byte without reconstructing prior state.

MP3 reconstruction is lossy: compressed spectral values are entropy decoded, requantized/scaled, possibly jointly stereo-reconstructed, transformed and synthesized into PCM. `dr_mp3` provides format decoding, not device output. The generic miniaudio converter/engine subsequently adapts rate/channels and spatial gain. A `.mp3` filename is checked by decoding/probing; an invalid or truncated file causes failure or a short read, not an automatic successful sound.

6.7.12 Generators

`ma_waveform` synthesizes sine/square/triangle/sawtooth-style periodic waves using configured amplitude/frequency/rate and persistent phase/time. `ma_pulsewave` adds pulse width/duty behavior. `ma_noise` supplies white, pink and brownian noise with seed/random state and per-channel history/filtering where required. Their data-source interfaces permit reads without a finite file. Setters change parameters; seek/cursor semantics are different from reopening a recorded asset. White noise is uncorrelated random output; pink and brownian variants apply frequency/history shaping. These families are compiled under generation support but Arrakis creates none of them: rumble is an asset, not synthesized brown noise here.

6.7.13 Resource Manager: Registry, Caches, Streaming, and Lifetime

The resource manager lives at lines 69309-73426, with declarations at 10297-10614. Config initialization at 69969 defaults to unknown output format, zero channels/rate (defer resolution), one worker thread, and a bounded job queue. The engine's internal manager overrides decoded format to f32 and decoded rate to engine rate while leaving decoded channels at zero to preserve useful native-channel/spatialization behavior.

The registry hashes paths (default hash seed **42**) and stores reusable buffer nodes in a search-tree structure. Loading the same nonstreamed path can share encoded or decoded backing data with reference counting; sound instances still

have independent playback state/cursors. Registering preloaded encoded or decoded data avoids repeated file I/O, but caller-supplied registered data has its own lifetime contract.

Flag families are `STREAM = 0x1`, `DECODE = 0x2`, `ASYNC = 0x4`, `WAIT_INIT = 0x8`, `UNKNOWN_LENGTH = 0x10`, and `LOOPING = 0x20`. Streaming uses paged/double-buffered decoded data so worker threads can read/decode/refill without a full file-sized allocation. Nonstreaming without `DECODE` keeps compressed/encoded bytes in memory; `DECODE` trades larger memory for less mixer decoding work. `ASYNC` queues loading/decoding instead of completing all work on the caller. `WAIT_INIT` establishes initial usable format/data even when later completion is asynchronous.

Typed jobs load/free a shared buffer node, load/free an instance buffer, page decoded data, load/free/page a stream, or seek a stream. Order/execution counters, notification/fence state and result fields coordinate initialization, future pages and destruction. A stream cannot free its decoder/page memory while a queued job still accesses it. Free/uninit must wait or otherwise honor those outstanding jobs. Job-thread shutdown posts quit/cancellation and joins threads before freeing queue/manager storage.

The manager API exposes register/unregister, buffer/stream/source init/uninit/copy, read/seek/format/cursor/length/loop controls and explicit process-next-job for application-managed execution. Custom VFS and custom decoder backends plug in at this level. On single-threaded Emscripten the engine has special job-processing behavior in its callback; that is not the usual Windows resource-manager thread model.

6.7.14 Node Graph and Every Built-In Node Family

Declarations 10615-11107; implementation 73427-76536. A graph mixes audio by pulling frames from its endpoint. Nodes have input and output buses, compatible channel counts, process vtables, state, times, gains and caches. Each input bus can receive several output buses; those sources are mixed before the destination process. A splitter's multiple outputs can feed distinct downstream branches. Channels must match at attachments; graph connections are not arbitrary byte-stream joins.

The implementation traverses upstream attachments, caches/mixes blocks, handles nodes with different consumed/produced rates, accounts for node start/stop scheduling and per-bus volume, and produces silence where required. Output-bus attachment lists are doubly linked with synchronized iteration/refcounts so detachment can wait for readers before destruction. This is why `ma_sound_uninit` first detaches its node. Feedback cycles should not be treated as a supported general-purpose cyclic graph merely because nodes can be connected.

The default node-cache capacity is **480 frames per bus** and default premix stack size is **524288 bytes per channel**, as named near 73492-73496. These are implementation/configuration defaults; engine device processing size can influence graph batching. Node caches are not the application's graphics frame buffers.

Node family	Role
Graph endpoint/base node	Common state, scheduling, bus attachments, pulling/mixing and endpoint output.
Data-source node	Reads a <code>ma_data_source</code> , emits PCM, optionally loops; source must remain valid until detached/uninitialized.
Splitter node	Copies/routes an input to multiple output buses for parallel processing.
Biquad node	Wraps a general coefficient filter in graph processing.
Low-pass node	Wraps the low-pass DSP family.
High-pass node	Wraps high-pass DSP.
Band-pass node	Wraps band-pass DSP.
Notch node	Wraps narrow rejection filtering.
Peaking node	Wraps parametric/peaking equalization.
Low-shelf node	Wraps low-frequency shelf equalization.

Node family	Role
High-shelf node	Wraps high-frequency shelf equalization.
Delay node	Wraps stateful delayed feedback/output mixing.

Node flags express passthrough (0x1), continuous processing (0x2), allow-null input (0x4), differing processing rates (0x8) and silent output (0x10). They guide graph traversal/caching and callback contracts; they do not enable a physical device backend. Stateful effect nodes need their own DSP heap/register cleanup when removed.

6.7.15 Engine, Engine Nodes, Sounds, and Groups

Engine definitions 76537-79893 compose the graph and resource manager with device output. Config initialization at 77455 chooses one listener, default mono expansion, and linear resource/pitch resampling. Initialization at 77521 zeroes output storage, copies config/callbacks, optionally allocates and initializes an f32 playback device, resolves channel count/rate, initializes graph, validates listener count against `MA_ENGINE_MAX_LISTENERS = 4`, creates listeners, selects gain-smoothing time, creates/configures an internal resource manager when needed, and starts the engine last unless `noAutoStart` is set. Error labels unwind the portions reached; exact ownership/error behavior should be checked in source when changing this vendor version.

The internal device callback at 77472 reads `ma_engine*` from device user data and calls `ma_engine_read_pcm_frames`. That pulls the graph and writes the device's requested frame block independently of the render loop. The engine manages clipping itself and disables redundant device presilencing/clipping when it creates its device.

An engine node supplies gain, pitch resampling, spatialization, fader state, listener choice, mono expansion and caches around node processing. A `ma_sound` adds a data source, seek/end/loop state, processing cache and optional end callback. File initialization allocates a resource-manager source, initializes it, sets ownership, and creates/attaches the sound node. A group is essentially a sound-like engine node without a data-source voice, accepting other voices and applying shared controls. Group controls mirror sound controls for volume, pitch, pan, spatial configuration and timed fades.

APIs cover explicit device/manager/log retrieval, engine read/start/stop/time/volume, listener position/direction/up/velocity/cone/enabled state, sound/group init/uninit/control, data-source access, scheduled starts/stops in frames/milliseconds, fades, looping, seeking, cursor/length, and play-once inlined sounds. `ma_engine_play_sound` internally manages a temporary/inlined sound list and reclamation; Arrakis instead owns eight explicit sounds. Seeking is deferred via an atomic target, and end-state handling can rewind on restart. Setting master gain to zero does not remove nodes or stop consumption.

Owned device teardown precedes graph teardown to stop callback access. Sound teardown precedes backing-source release to stop graph readers. External device/resource-manager ownership differs from internal ownership: a caller must retain external objects while engine/sounds use them and release them in an order consistent with the docs. The wrapper's explicit stable global storage and sound-before-engine shutdown follow the core required order, without implementing a general lifetime-safe reusable audio-owner class.

6.8 GLAD: Generated Loader, Every Version, and Platform Branch

6.8.1 What This File Implements and What It Does Not

`third_party/glad/glad.c` is generated with API `gl=4.6`, core profile, loader enabled, and **an empty selected-extension list**. Its provenance records `Local files: False`, `Omit khrrplatform: False`, and `Reproducible: False`. It includes `<glad/glad.h>` supplied by the project's configured external include directory. This `.c` file is not the OpenGL renderer implementation and not the driver: its function pointers lead to driver-provided implementations in the current context.

Arrakis explicitly uses `gladLoadGLLoader((GLADloadproc)glfwGetProcAddress)` after GLFW creates and makes an OpenGL context current. That uses GLFW's resolver, not GLAD's optional direct-system-library

`gladLoadGL()` entry. Both paths are nevertheless present and documented because the request includes the entire supplied file.

6.8.2 Complete GLAD Source Coverage

Original lines	Contents
1-26	Generator provenance/options and C/header includes
27-157	Procedure resolver declaration; Windows/UWP or dlopen platform loader; resolver fallback; <code>gladLoadGL</code>
158-171	Version struct/state, max loaded version, extension storage
172-205	Extension enumeration/storage
206-216	Extension-storage cleanup
217-257	Exact extension-name membership helper
258-276	Nineteen <code>GLAD_GL_VERSION_*</code> flags, all initially zero
277-975	Alphabetically arranged typed <code>glad_gl*</code> function-pointer globals, initially null
976-1735	Nineteen version-specific loading functions, individually mapped below
1736-1742	Selected-extension discovery wrapper; this generated selection is empty
1743-1803	Current-context version parsing and all version-flag tests
1804-1832	Public caller-resolver entry, core loads, extension handling and boolean success
1833	Original trailing blank line; absent after relocation

6.8.3 System Library Opening, Resolution, and Closing

Windows/Cygwin uses an `HMODULE libGL` and a typed pointer to `wglGetProcAddress`. The preprocessor manages `APIENTRY` and includes `<windows.h>`. MSVC SDK detection conditionally includes `winapifamily.h`; a non-desktop app partition defines `IS_UWP`. On desktop, `open_gl` calls `LoadLibraryW(L"opengl32.dll")`, obtains `wglGetProcAddress` using `GetProcAddress`, and succeeds only if both the library and resolver are available. UWP's disabled desktop opening path returns zero. `close_gl` calls `FreeLibrary` if non-null and clears `libGL`.

Non-Windows uses `<dlfcn.h>`, a `void* libGL`, and on non-Apple/non-Haiku platforms a `glXGetProcAddressARB` pointer. Apple attempts these paths in exact order:

1. `../Frameworks/OpenGL.framework/OpenGL`
2. `/Library/Frameworks/OpenGL.framework/OpenGL`
3. `/System/Library/Frameworks/OpenGL.framework/OpenGL`
4. `/System/Library/Frameworks/OpenGL.framework/Versions/Current/OpenGL`

Other non-Windows platforms attempt `libGL.so.1`, then `libGL.so`. Each is opened with `RTLD_NOW` | `RTLD_GLOBAL`. Apple/Haiku return success as soon as a library opens; other platforms require `dlsym(libGL, "glXGetProcAddressARB")` to succeed. `close_gl` uses `dlopen` and clears the pointer. The loop returns immediately after the first opened library's resolver check; an opened library without the required resolver is not automatically followed by testing the next name. The failure path's exact cleanup is worth reading before embedding this generated direct-library helper in another host.

`get_proc(const char* namez)` initializes result null, rejects null `libGL`, tries the platform context resolver where compiled, then falls back to Windows `GetProcAddress` or POSIX `dlsym` only when the first result is null. It returns the raw procedure address. The supplied Windows helper does not explicitly reject the unusual non-null sentinel values some `wglGetProcAddress` implementations can return. Arrakis relies on GLFW's resolver instead.

`gladLoadGL()` calls `open_gl`; on success calls `gladLoadGLLoader(&get_proc)`, then `close_gl`; returns the loader status. It does not create an OpenGL context. Resolution remains context dependent, and closing the helper's temporary module handle should not be interpreted as destroying GLFW's context/driver lifetime. The application must keep the context alive for graphics calls and must not assume pointer validity after context/provider changes.

6.8.4 Function Pointer Storage and Assignment Semantics

Every global declaration has the form `PFNGL...PROC glad_glName = NULL;`. The typedef from `glad.h` encodes the driver function's return type, parameters and platform calling convention. The header normally aliases familiar `glName` spellings to these globals. The declaration does not implement that OpenGL operation; it reserves a call target.

Every generated loading assignment has the form `glad_glName = (PFNGL...PROC) load("glName")`. Its one parameter is `GLADloadproc load`, the caller's resolver taking a symbol name. Its only branch is the version guard `if (!GLAD_GL_VERSION_M_N) return;`, followed by a fixed sequence of lookups. There is no per-assignment validation, wrapper around arguments, shader compilation, mathematical rendering work, GPU object allocation, or error checking here. Two appearances of a symbol in successive version blocks mean it can be assigned again, not that two GPU implementations are compiled.

The globals are process-global and this loader is not a multi-context dispatch table with automatic context switching. Reloading for a new context updates shared targets. Version success alone is not a proof that every pointer needed by the game is non-null. Unloaded/unsupported pointers must not be called.

6.8.5 Every Generated Core-Version Loading Family

These ranges are exact boundaries of the generated functions, not a generic list of OpenGL release headlines. Every assignment in a range resolves a driver function; the described operation is performed **later by the driver when called**, not by GLAD.

Loader and lines	Loaded functional families and meaning
<code>load_GL_VERSION_1_0</code> , 976-1026	Rasterization state (culling/front face/hints/line/point/polygon/scissor), texture parameters and 1D/2D images, draw/read buffers, clear values/masks, enable/disable, finish/flush, blending/logic/stencil/depth, pixel packing/readback, scalar/vector state queries, errors/string queries, texture inspection, depth range and viewport. This generated core subset does not supply classic immediate-mode <code>glBegin</code> rendering.
<code>load_GL_VERSION_1_1</code> , 1027-1042	Array/indexed draws, polygon offset, texture copy/subimage updates, bind/generate/delete/is-texture. These provide object-oriented texture lifetime and bulk geometry submission.
<code>load_GL_VERSION_1_2</code> , 1043-1049	Draw-range indexed draw and 3D texture image/subimage/copy operations.
<code>load_GL_VERSION_1_3</code> , 1050-1061	Active texture unit, sample coverage, compressed texture image/subimage/get for 1D/2D/3D. Texture-unit selection is separate from binding/creating texture objects.
<code>load_GL_VERSION_1_4</code> , 1062-1073	Separate blend factors, multidraw arrays/elements, float/integer point parameters, blend color/equation. Multidraw combines submission descriptions; GLAD merely resolves the entry.
<code>load_GL_VERSION_1_5</code> , 1074-1095	Query object create/delete/begin/end/results and buffer object bind/create/delete/data/subdata/readback/map/unmap/parameter/pointer queries. Buffer data calls later allocate/update GPU-visible storage.

Loader and lines	Loaded functional families and meaning
load_GL_VERSION_2_0, 1096-1191	Separate blend equations, multiple render targets, per-face stencil; shader/program create/source/compile/attach/link/validate/use/delete/reflection/logs; float/integer scalar/vector and square-matrix uniforms; vertex attribute values/pointers/enabling/query. Shader failure handling belongs to application calls and logs, not loader initialization.
load_GL_VERSION_2_1, 1192-1200	Six rectangular float uniform matrix forms: 2x3, 3x2, 2x4, 4x2, 3x4, 4x3.
load_GL_VERSION_3_0, 1201-1287	Indexed state/masks, transform feedback and buffer-base/range binding, color clamp, conditional rendering, integer vertex attributes, unsigned uniforms, fragment-output binding, integer texture parameters, typed clears, indexed strings, renderbuffers/framebuffers and attachments/status/blit/multisample/layer, range mapping/flush and vertex array objects. This contains Arrakis's framebuffer/VAO-era infrastructure.
load_GL_VERSION_3_1, 1288-1305	Instanced draws, buffer textures, primitive restart, buffer copies, uniform index/block reflection/binding and repeated base/range/indexed integer lookups. Uniform blocks share packed state across draw programs.
load_GL_VERSION_3_2, 1306-1327	Base-vertex indexed draw variants, provoking vertex, sync object fence/waits/delete/query, 64-bit state/buffer queries, layered framebuffer texture, multisample textures and sample masks. Sync functions govern CPU/GPU completion, not audio thread synchronization.
load_GL_VERSION_3_3, 1328-1388	Indexed fragment outputs, sampler-object lifetime/parameters, timestamp/query-counter and 64-bit results, vertex attribute divisors for instancing, packed vertex/texture/normal/color attribute variants. The supplied file contains some packed legacy-named targets despite its core provenance; presence is not a guarantee they are valid in every core context.
load_GL_VERSION_4_0, 1389-1437	Sample shading, per-draw-buffer blending, indirect draws, double scalar/vector/matrix uniforms and queries, shader subroutine reflection/selection, tessellation patch parameters, transform feedback objects/stream draws, indexed queries.
load_GL_VERSION_4_1, 1438-1529	Shader/compiler binary/precision controls, float depth range/clear, program binaries/parameters, separate program pipelines/stage selection/validation/logs, all direct program-uniform forms (float/int/uint/double and matrices), double vertex attributes/pointers, viewport/scissor/depth-range arrays/indexed forms and indexed float/double queries.
load_GL_VERSION_4_2, 1530-1544	Base-instance instanced draws, internal-format queries, atomic counter buffer reflection, image texture binding, memory barriers, immutable texture storage, instanced transform feedback/stream drawing. Barriers control visibility of GPU memory operations.
load_GL_VERSION_4_3, 1545-1591	Clear buffer data/subdata, compute dispatch/direct-indirect, image copies, framebuffer parameter configuration, 64-bit format queries, invalidate texture/buffer/framebuffer storage, multidraw indirect, program-interface/resource reflection and shader storage binding, ranged buffer textures, multisample storage, texture views, separate vertex-binding/format APIs and debug message/group/object-label APIs.
load_GL_VERSION_4_4, 1592-1603	Immutable/persistent-capable buffer storage, texture clears, multibind buffer base/range, textures, samplers, images and vertex buffers. Capability flags supplied by later callers decide persistence/coherency, not loader assignment.

Loader and lines	Loaded functional families and meaning
load_GL_VERSION_4_5, 1604-1728	Clip control; direct-state-access transform feedback/buffer/framebuffer/renderbuffer/texture/vertex-array creation and named operations; texture unit/image/storage/subimage/mipmap/readback APIs; named object/map/query APIs; sampler/pipeline/query creation; query-buffer results; regional barriers; robustness reset/bounded readback/uniform calls, several legacy-named bounded calls, texture barrier. Direct-state access operates on explicitly named objects rather than implicit bind state.
load_GL_VERSION_4_6, 1729-1735	Exactly four resolutions: glSpecializeShader, glMultiDrawArraysIndirectCount, glMultiDrawElementsIndirectCount, glPolygonOffsetClamp. Shader specialization supplies SPIR-V entry/specialization data to the driver; indirect-count draws read draw counts; polygon offset clamp adds a bound.

GLAD includes versions through 4.6 so the application can resolve newer operations where available. That does not mean Arrakis requires or requests a 4.6 context, or that it uses compute, tessellation, SPIR-V, persistent mapping and every other loaded family. Shader language versions, requested GLFW context and actual driver version are separate facts.

6.8.6 Extension Storage, Matching, and Empty Selection

GLVersion starts {0,0}. max_loaded_major/minor, exts, num_exts_i, and exts_i hold discovery state. _GLAD_IS_SOME_NEW_VERSION is compiled when suitable GL/ES 3.0 declarations exist.

get_exts takes the legacy path for loaded major below 3: glGetString(GL_EXTENSIONS) supplies one driver-owned space-separated string. Otherwise it obtains GL_NUM_EXTENSIONS, allocates a char** array, queries each glGetStringi(GL_EXTENSIONS, index), allocates len+1 bytes and copies a null-terminated name. Those copied strings are GLAD-owned; the legacy string is not. Array allocation failure returns zero. Individual string allocation failures leave a null element. The source also returns failure when a modern context reports zero extensions and exts_i remains null; this is a generated-loader edge case, not proof the GL context is absent.

free_exts frees every copied element (null is safe), frees the array, and clears exts_i. has_ext(ext) uses strstr plus boundaries in legacy mode: a match must begin at the string start or after a space and end at space or terminator. This avoids accepting GL_F00 inside GL_F00BAR. Modern mode iterates copied names with exact strcmp, skipping null entries. Null requested/legacy strings reject membership.

find_extensionsGL calls get_exts, returns zero on failure, references has_ext only to silence unused-function concerns, frees extensions, then returns one. **No selected extension flags and no extension loader blocks are generated** because the selected extension list was empty. The code enumerates extensions but does not expose a complete extension registry to Arrakis. There is therefore no missing list of hundreds of extension-loading functions to explain in this particular file; they are genuinely not present.

6.8.7 Version Parsing and Public Loader Success

find_coreGL obtains glGetString(GL_VERSION); null returns immediately. It strips the first matching prefix among "OpenGL ES-CM ", "OpenGL ES-CL ", and "OpenGL ES ", then scans %d.%d using sscanf_s on MSVC or sscanf otherwise. Major/minor are stored in GLVersion and maximum-loaded state. The source does not check the scan's return count before using locals; valid driver version strings are assumed.

For every supported version M.N, the exact flag test is (major == M && minor >= N) || major > M. Thus a 3.3 context sets flags 1.0 through 3.3 true and 4.x false. A reported version above 4.6 is capped in **max-loaded discovery state** to 4.6, while GLVersion records the reported version. That cap reflects generator coverage, not a request to downgrade a context.

gladLoadGLLoader(load) resets GLVersion, resolves glGetString first, fails if that pointer is null or its GL_VERSION query is null, calls version discovery, invokes all nineteen loaders in ascending version order (each

self-guards), invokes extension discovery, and returns `GLVersion.major != 0 || GLVersion.minor != 0`. It does not validate the resolver pointer before its first call, confirm every required graphics symbol, compile shaders, or check framebuffer completeness. On a failed/repeated load, not every old global target is proactively cleared; callers should not keep using stale state just because some pointers remain non-null.

The game checks the returned boolean and terminates graphics setup on failure. A current context must exist before loading. A successful 4.6-capable loader build running against a 3.3 context is normal: unsupported later blocks simply do nothing. The renderer must limit calls to the supported/requested API subset.

6.9 Historical Vorbis Study: Removed, Never Integrated

6.9.1 Complete Source Coverage Map

These are historical original `stb_vorbis.c` line numbers recorded from inspection before cleanup. The unused 5,584-line file has been removed; it is not remaining project code, not compiled, and not part of the current-source appendix. This optional decoder study explains the previously supplied file and the Ogg integration requirements. Restoring it would be a future codec feature, not a missing requirement of the current WAV/MP3 game.

Lines	Contents and purpose
1-68	Decoder version 1.22, authors/history, explicit codec/seek limitations
69-171	Header guard/linkage, allocator/info/comment structs, shared handle/query/close APIs and thread-safety rules
172-246	Pushdata declarations and detailed consumed-byte/output/flush contracts
247-371	Pull/file/memory/seek/length/frame/sample/whole-file declarations, buffer sizing and channel coercion
372-419	Error enum, header closure, implementation boundary
420-662	Compile configuration, defaults, includes, endian/inlining/alloca/CRT portability and implementation setup
663-937	Internal codebook/floor/residue/mapping/mode/page/decoder-state types, packet/sample/buffer state, error/allocation macro groundwork
938-1232	Block arrays and permanent/temporary allocator helpers, CRC32, bit reversal/integer log/float unpacking, canonical/sorted/accelerated Huffman construction
1233-1336	Header validation, vector-quantization lookup size, twiddle/window/bit-reverse tables, blocksize setup, floor-neighbor/sorting helpers
1337-1633	File/memory byte access/offsets, Ogg capture/page parsing, packet/lacing/segment handling and bit accumulator
1634-1934	Huffman scalar fast/slow decoding and vector/codebook expansion into output/residue arrays
1935-2082	Floor prediction and inverse-dB lookup table, line rasterization into spectral gains
2083-2407	Residue types and partition/codebook decoding, spectral vectors, reference/conditional transform groundwork
2408-3058	Optimized inverse-MDCT stages, butterflies, rotations, permutations and transform reconstruction

Lines	Contents and purpose
3059-3518	Window lookup, floor application, packet-mode/short-long block decoding, channel coupling inversion, residue/floor combination, inverse transforms, overlap/add and initial-frame priming
3519-4207	Push whole-packet availability and complete decoder-start/setup parsing: identification/comments/codebooks/time/floor/residue/mapping/modes, validation/allocation
4208-4340	Deep state cleanup, close/init/allocate and info/comment/error/sample-offset queries
4341-4557	Push flush, CRC page resynchronization, push-frame decoding/open and file-offset query
4558-5027	Pull seeking: Ogg page search/probes, coarse/binary-guided location, frame/sample-exact refinement, seek start and length queries
5028-5120	Pull float-frame decode and file-section/file/filename/memory opening
5121-5425	Channel assignment/conversion tables, float-to-short clipping/mixing, frame/sample short APIs and whole-file filename/memory decode
5426-5479	Caller-buffer float sample/interleaved APIs, buffered remainder handling, pull implementation closure
5480-5543	Detailed historical changes and implementation guard closure
5544-5584	MIT/public-domain alternative license text

6.9.2 Public Structures, Modes, and Ownership

`stb_vorbis*` is an opaque decoder handle. Unlike miniaudio's transparent outer engine structs, application code does not allocate its internal decoder struct by ordinary public field initialization. `stb_vorbis_alloc` contains `char* alloc_buffer` and `int alloc_buffer_length_in_bytes`; a caller-provided block must remain alive until close and be large enough for setup and temporary decode memory. Without it, startup uses heap allocation and frame temporaries commonly use stack `alloca`.

`stb_vorbis_info` reports sample rate, channel count, permanent setup memory, setup temporary memory, frame temporary memory and maximum frame size. `stb_vorbis_comment` reports a vendor string, comment-list length and borrowed comment pointers. `get_info` copies scalar information; comments and frame outputs point into decoder-owned storage. `get_error` obtains and clears the last stored error. `close` releases owned internal allocations and, when configured, the opened file. An individual handle is not safe for simultaneous decode calls on multiple threads; separate handles can operate independently.

Push mode accepts successive encoded-byte windows. `open_pushdata` parses complete initial headers or returns null with an error such as `VORBIS_need_more_data`; on success it reports bytes consumed.

`decode_frame_pushdata` reports consumed **encoded bytes** separately from output **samples per channel**, and returns planar `float**` output through a `float***` output parameter. Zero consumed/zero output means more bytes are needed; consumed bytes with zero samples can mean resynchronization or initial-frame discard; consumed bytes with samples means a decoded frame. The first audio frame after open is discarded as part of Vorbis overlap priming. Internal output is transient and overwritten by later decoding; do not free or modify it.

`flush_pushdata` says the next encoded block is noncontiguous and resets the scanner/overlap continuity so the decoder searches for a valid page. The caller owns buffering and seeks its own source; flush alone does not select an exact PCM frame. Pull mode instead owns traversal of a complete memory buffer or a `FILE*` section. Open-file parameters specify close-on-free behavior and optional section length; external repositioning of an active owned stream confuses the decoder.

Frame APIs return a codec-frame-sized planar/interleaved output; sample APIs fill caller buffers across frame boundaries and cache unused samples. Interleaved capacity arguments are counts of scalar floats/shorts, while return values are samples **per channel**. Whole-file short decoders allocate a new interleaved buffer and return sample count or failure; the caller frees that buffer. Float sample APIs and integer coercion APIs do not all apply identical channel-mixing rules.

6.9.3 Container, Entropy Decode, Floor, Residue, and Mapping

Ogg is the container. Page parsing recognizes the capture pattern, version/flags, granule position, stream serial/sequence, checksum and lacing/segment table. A lacing byte of 255 continues a packet; packet boundaries can span pages. Byte/bit readers distinguish encoded EOF from an incomplete push buffer. CRC32 tables/updates validate candidate pages during push resynchronization, where several apparent headers may overlap in corrupted/unrelated data.

Vorbis setup packets define codebooks, floor, residue, mapping and modes. Codebooks contain symbol code lengths, Huffman decode tables and optional vector-quantization lookup values. Initialization computes canonical codes with Vorbis bit ordering, a short-code accelerated lookup, and sorted slow-path tables. Scalar decode consumes a codeword to produce a symbol; vector decode converts a symbol/index into values added or interleaved into spectral residue. Fast lookup is an optimization of entropy decoding, not an alternate audio codec.

The supported floor-1 algorithm decodes a sparse spectral envelope. Neighbor prediction reconstructs control-point heights; integer line drawing and an inverse-dB table build frequency-bin gains. Residue decodes the remaining spectral detail with partition classes/codebooks and type-specific arrangement. Mapping selects submaps and channel coupling; reverse coupling reconstructs channel spectral coefficients. Applying the floor to residue yields the spectrum supplied to the inverse transform.

Header setup validates dimensions/counts/types before allocating permanent tables and working buffers. It rejects unsupported floor 0 and invalid mappings/types rather than treating them as a supported generalized format. Comments/vendor strings are metadata, not synthesis data. The code has many bounds/overflow/truncation checks, but reading them for this chapter is not an independent claim of vulnerability freedom.

6.9.4 Inverse MDCT, Windowing, and Overlap

Compressed Vorbis packets reconstruct frequency-domain coefficients. `inverse_mdct` converts a block's spectrum into time-domain audio using precomputed trigonometric twiddles, staged butterfly/rotation loops, bit-reversed ordering and final rearrangement. The reference/conditional transform paths and optimized helper loops compute the same codec transform; they are not unrelated game-specific math.

Short and long blocks use different window regions, selected by packet mode and previous/next-window flags. The Vorbis window shape is built using the codec's nested-sine taper, conceptually $\sin((\pi/2) * \sin(\pi * (i+0.5)/n)^2)$ over the rising half. Windowed adjacent blocks overlap/add to avoid discontinuities while permitting long-block compression and short-block transient response. `vorbis_finish_frame` combines retained previous-window samples with the current block, establishes valid output bounds, updates sample location and retains the next overlap. The first packet primes history; the final granule position can trim valid final output.

The decoder therefore requires retained state across frames. Reopening or seeking may need preroll/neighbor-frame decoding; simply inverse-transforming a random packet does not produce sample-exact continuous output. The declared absolute maximum frame output is 4096 samples per channel under the Vorbis I block-size constraints, but callers should use reported info/capacities and the actual returned count.

6.9.5 Push Resynchronization, Pull Seeking, and Conversion

Push resynchronization scans for candidate Ogg pages, incrementally checks CRC and tracks a limited number of overlapping candidates. Once it finds a valid stream/page/frame boundary it restores continuity and sample-position knowledge where possible. Consumed bytes can be less than the supplied block so a capture pattern split across calls is not lost. More input may be required even when some garbage was consumed.

Pull seeking searches/probes pages using byte position and granule/sample information to narrow an interval, then decodes/refines around the target. `seek_frame` permits a returned frame that contains the target; seek positions buffered sample output so sample APIs begin exactly at the requested sample; `seek_start` resets to the beginning. Length queries inspect stream/page information and return sample or seconds forms. The source documents 32-bit sample-position limits despite Ogg supporting 64-bit granule positions.

Integer conversion scales/clamps float values to signed short output and implements simple channel coercion. Requested mono can sum all source channels; requested stereo combines left/center and right/center assignments; requesting more than present fills extra channels with zero; other cases select available channels. The vendor explicitly warns that this is not high-quality general surround mixing. Buffer-based float readers manage channel copying and cached frame remainders separately, and should not be assumed to follow all short-output coercion rules.

6.9.6 Compile Switches, Exact Defaults, and Explicit Limits

Switch or default	Effect
<code>STB_VORBIS_HEADER_ONLY</code>	Emits declarations/header section only; used when implementations are compiled separately.
<code>STB_VORBIS_NO_PUSHDATA_API</code>	Removes push-data APIs and supporting scanner behavior.
<code>STB_VORBIS_NO_PULLDATA_API</code>	Removes pull APIs and implies no stdio/integer conversion.
<code>STB_VORBIS_NO_STDIO</code>	Removes file APIs; memory/push paths can remain.
<code>STB_VORBIS_NO_INTEGER_CONVERSION</code>	Removes short conversion/whole-file short APIs while float decode can remain.
<code>STB_VORBIS_NO_CRT</code>	Changes allocator/CRT assumptions and implies no stdio; caller-provided memory becomes essential where malloc is unavailable.
<code>STB_VORBIS_MAX_CHANNELS = 16</code>	Default compile-time decoder channel cap; container field's theoretical 255 limit does not override this build default.
<code>STB_VORBIS_PUSHDATA_CRC_COUNT = 4</code>	Four overlapping page candidates during push resynchronization.
<code>STB_VORBIS_FAST_HUFFMAN_LENGTH = 10</code>	Fast lookup uses a 10-bit prefix, nominally 1024 table positions; larger permitted values trade memory/cache behavior for fewer slow decodes.
<code>STB_VORBIS_FAST_HUFFMAN_INT</code> / default short table	Changes accelerated table entry width; default chooses <code>STB_VORBIS_FAST_HUFFMAN_SHORT</code> .
<code>STB_VORBIS_NO_HUFFMAN_BINARY_SEARCH</code>	Uses smaller/slower fallback lookup choices instead of the usual sorted-code search where applicable.
<code>STB_VORBIS_DIVIDES_IN_RESIDUE</code> , <code>STB_VORBIS_DIVIDES_IN_CODEBOOK</code>	Trade precomputed storage for runtime divide/index reconstruction.
<code>STB_VORBIS_DIVIDE_TABLE</code>	Optional floor integer-division lookup tradeoff; documented as disabled by default for small benefit.
<code>STB_VORBIS_NO_INLINE_DECODE</code>	Disables scalar fast-decoder inlining; useful for size/debugging tradeoffs.
<code>STB_VORBIS_NO_DEFER_FLOOR</code>	Synthesizes floor earlier rather than deferring, changing working-memory/processing behavior.
<code>STB_VORBIS_NO_FAST_SCALED_FLOAT</code> , <code>STB_VORBIS_BIG_ENDIAN</code>	Select safe/fast float-to-int conversion and endian handling.
<code>STB_VORBIS_CODEBOOK_SHORTS</code>	Explicitly rejected with <code>#error</code> because prior behavior could produce incorrect results.

The top-of-file limitations are literal: no floor 0 (older pre-2004 streams), ignored lossless sample truncation at the beginning, no concatenated multiple Vorbis streams, and 32-bit sample positions limiting high-rate long seeks (approximately six hours at 192 kHz). It is a Vorbis decoder, not an encoder, Opus decoder, playback backend, resampler, game mixer or replacement for miniaudio's engine. None of these compile switches are currently selected by the game because the file is not part of its compiled path.

6.10 API Reference and Annotated-Appendix Strategy

6.10.1 Index All Code Without Replacing Explanation with Symbol Lists

The prose above explains behavior by family; the exact source appendix supplies the full declarations, constants, generated assignments, tables and branches. A maintainable API reference should index a symbol by **source path, original line, family, declaration, definition, conditional guards, ownership, callback/thread restrictions, parameters and result semantics**. A bare alphabetical dump is helpful for lookup but cannot explain interactions such as a sound holding a resource-manager source or a graph detach waiting for callback readers.

For miniaudio, search MA_API declarations in the public region and matching definitions in the implementation. Many symbols occur twice; retaining both locations avoids mistaking a prototype for an implementation. Also index internal static helpers by family, structs/enums/macros and embedded `ma_dr_*` functions. Preprocessor guards should be recorded because source inclusion, compile inclusion and runtime selection are three different things. For GLAD, pair each `glad_gl*` global declaration with every `load("glName")` assignment and its enclosing core-version guard; the actual OpenGL signature is in the external `glad/glad.h`. For `stb_vorbis`, public declarations and matching implementation definitions plus static decode helpers need separate entries.

6.10.2 Family-Level API Lookup Index

Symbol prefix / group	Public/source entry region	Why consult it
ma_version*, ma_result_description, allocation helpers	4508; 6112-6182; definitions 12298, 58926 onward	Version/diagnostics, allocator/free matching and PCM byte sizing
ma_log_*	4516-4590; definitions around 13572	Callback logging and registration lifetime
ma_biquad_*, ma_lpf*, ma_hpf*, ma_bpf*, ma_notch*, ma_peak*, ma_loshelf*, ma_hishelf*	4591-5003; 47164-50374	Filter coefficients/configs, per-channel state, reinit/processing/preallocation
ma_delay_*, ma_gainer_*, ma_panner_*, ma_fader_*, ma_spatializer*	5004-5317; 50375-53026	Time/gain/pan/spatial behavior and channel-state memory
ma_linear_resampler_*, ma_resampler_*	5331-5523; 53027-54276	Ratio/rate, custom vtables, latency and consumed/produced frame counts
ma_channel_converter_*, ma_data_converter_*, ma_convert_*, channel-map helpers	5524-5830; 54277-58096	Format/rate/channel composition and buffer capacities
ma_data_source_*, ma_audio_buffer*, ma_paged_audio_buffer*	5831-6025; 59138 onward	Borrowed/owned data, cursor/seek/loop/range and paging lifetime
ma_rb_*, ma_pcm_rb_*, duplex buffer	6026-6111; 58097-58922	Producer/consumer buffering and acquire/commit rules
ma_spinlock_*, ma_mutex_*, ma_event_*, ma_semaphore_*, ma_fence_*, notification APIs	6183-6335; 17544 onward	Cross-thread synchronization and callback-safety requirements
ma_slot_allocator_*, ma_job_*, ma_job_queue_*	6336-6593; 18579-19470	Bounded work storage, worker dispatch and shutdown
ma_context_*, ma_device_*, backend IDs/configs	6594-9751; 19471-44574	Device enumeration/init/start/stop/native negotiation and platform guards
PCM copy/silence/clip/volume/mix/interleave helpers	9752-9865; 44575-47163	Samples/frames, signed silence, clipping and conversions
ma_vfs_*, ma_default_vfs_*	9866-9944; 60904-61933	Custom/default file streams and file ownership
ma_decoder_*, ma_decoding_backend_*	9945-10110; 62840-67830	Codec probing/output conversion, custom decoding, read/seek/length
ma_encoder_*	10111-10169; 67831-68147	WAV write/finalization contract
ma_waveform_*, ma_pulsewave_*, ma_noise_*	10170-10296; 68148-69308	Infinite/generated data sources, phase/random state
ma_resource_manager_*	10297-10614; 69309-73426	Encoded/decoded cache, stream pages, worker jobs/refcounts
ma_node_*, ma_node_graph_*, source/splitter/filter/delay nodes	10615-11107; 73427-76536	Graph pull/attachment/state/bus contracts
ma_engine_*, ma_engine_node_*, ma_sound_*, ma_sound_group_*	11108-11535; 76537-79893	High-level playback, listener, pitch/gain/event/lifetime APIs used by Arrakis
ma_dr_wav_*	61934-62368; 79908-84837	WAV container metadata, PCM/ADPCM reads, conversion/write helpers

Symbol prefix / group	Public/source entry region	Why consult it
ma_dr_flac_*	62369-62662; 84838-92696	Lossless subframes/residuals/metadata/channel decorrelation/seek
ma_dr_mp3*	62663-62839; 92697-95804	MPEG decode/reservoir/synthesis and MP3 wrapper APIs
ma_stbvorbis_*	65330-66159, conditional	Optional callback/push/file/memory Vorbis bridge
gladLoadGL, gladLoadGLLoader, version/ext helpers	GLAD 27-257, 1736-1832	Loading success/context/platform/extension behavior
glad_gl*, load_GL_VERSION_*	GLAD 277-1735	Every resolved graphics symbol and version guard
Historical stb_vorbis_* and decode helpers	Removed source, former lines 69-5479	Historical codec study only; absent from current code/appendix/build

6.10.3 Auditable Limits and Practical Recommendations

The source listings and line maps establish coverage of the supplied files, including unused vendor branches. They do not establish audible playback on every machine, validity of every sound's binary contents, support for absent optional assets, correctness of all native API drivers, or a separate explanation of every generated graphics signature supplied by the external GLAD header. External GLAD/GLFW/GLM headers and actual driver/backend libraries are not reproduced by pretending they are contained in these four vendor files.

For verification, keep three results separate: engine initialization, per-file [AUDIO] Loaded messages, and actual audible/spatial behavior. Useful checks include running with no device; removing/renaming an optional primary asset in a controlled test; launching from a supported and unsupported working directory; comparing camera movement with fixed source position; muting across rescue/breach edges; restarting a mission during active one-shots; and observing boost gain/pitch thresholds. Those are recommended tests, not tests claimed to have been executed for a documentation-only chapter.

If Ogg fallbacks are retained as an advertised feature, integrate and test an actual Vorbis backend, or replace/remove those fallback expectations. The organized package currently retains the eight WAV/MP3 primaries and removed the unused stb source; it is not needed in the executable. Archive/library-license handling is separate from compilation necessity. Keep the current line-numbered appendix with its vendor version identifiers so future library updates do not silently invalidate this chapter's references. Historical references here are not a promise that removed files remain available.

7. The Documentation Generator, Line by Line

Purpose and Boundaries

`tools/generate_docs.py` produces the PDF requested for this project. It renders authored Markdown explanation chapters, generates page numbers and navigation, and appends complete numbered source/configuration listings. It also writes a machine-readable snapshot manifest. It does not infer the meaning of the game through artificial intelligence, execute the game, prove the prose correct, or automatically update descriptions after gameplay changes. The written chapters must be maintained when behavior changes; source hashes make a stale snapshot detectable.

The generator deliberately uses Python plus ReportLab instead of requiring a browser, LaTeX distribution, Node.js, or an online conversion service. The PDF is created locally. `tools/requirements.txt` contains two constraint lines: `reportlab>=4.2, <5` allows compatible 4.x renderer versions, and `pypdf>=5, <7` allows supported PDF-inspection versions. The lower bounds request available functionality; the upper bounds avoid silently adopting a major-version API change. Pillow is brought in as a transitive ReportLab dependency and is not a game dependency.

Lines 1-23: Module Setup and Imports

The module docstring describes the file's purpose and later supplies command-line help. `from __future__ import annotations` postpones annotation evaluation; types such as `List[str]` communicate expected values without affecting game execution. `argparse` defines command-line options and user-facing errors. `hashlib` computes SHA-256 fingerprints. `json` serializes the snapshot manifest. `re` matches the supported Markdown syntax. `textwrap` splits long text without truncating it. `datetime` and `timezone` produce a UTC generation date/time. `Path` joins and resolves paths independently of the current working directory. XML escaping protects Paragraph text from treating source characters such as `<` or `&` as formatting markup.

The ReportLab imports provide RGB/hex colors, centered alignment, the A4 page size, paragraph styles, millimeter conversion, a base multi-pass document, text frames, page templates, page breaks, formatted paragraphs, literal preformatted blocks, spacing, tables, table styling, and a table of contents. These classes divide responsibilities: Flowables are pieces of page content, a Frame defines where pieces can fit, and a PageTemplate defines recurring page furniture.

Lines 25-39: Exact Input Lists

`ROOT` resolves this script's actual location, takes its parent `tools` directory, then its parent repository directory. This makes normal input lookup independent of the shell's current directory. `CHAPTERS` is an ordered tuple of all seven required chapter filenames. A tuple fixes the desired reading sequence rather than relying on operating-system directory enumeration. `SOURCE_PATHS` explicitly lists application, test, build, editor, dependency, generator, and vendor files. No generated build files or removed model packs are included. Miniaudio's implementation unit is listed before GLAD and the large miniaudio header, so the most oversized source reference appears at the end instead of interrupting explanations.

These lists are intentionally explicit. Adding a new source file requires adding it to the listing and writing its explanation; the script does not pretend it can determine which newly added folder is meaningful. Before rendering, every listed input is checked. A missing chapter or source causes a clear error rather than an incomplete PDF that silently omits the file.

Lines 42-54: inline, Safe Inline Formatting

`inline(text)` receives ordinary text and returns the limited markup understood by ReportLab's Paragraph renderer. `re.split` separates backtick-delimited inline-code fragments while retaining the matched fragments. Each fragment is examined in order. A backtick pair is removed and its literal content escaped, then wrapped in a Courier font tag. This makes identifiers/paths visually distinct and ensures a code expression containing XML characters is not interpreted as markup.

Non-code fragments are escaped first. The bold substitution turns `**text**` into a `<b>` span. The Markdown-link substitution renders the readable label followed by the destination in parentheses; it does not fetch that destination or embed remote content. Appending results to a list and joining once avoids repeatedly growing a string for every fragment. The function deliberately does not implement the complete CommonMark standard, nested Markdown, or arbitrary raw HTML. Unrecognized markup remains text instead of enabling unexpected processing.

Lines 57-68: `source_rows`, Preserve Every Source Line

`source_rows(content, width=100)` converts source text into printable lines. `splitlines()` obtains physical source lines; enumeration begins at one to match editor line numbers. Tabs expand to four spaces to give a consistent printed indentation. `textwrap.wrap` caps code fragments at 100 characters, preserves whitespace, permits splitting a very long uninterrupted identifier/string, and avoids additional hyphen-based breaks. An empty original line becomes one empty chunk rather than disappearing.

The first fragment receives a six-character right-aligned line number and `|` separator. Every continuation receives spaces and `>` instead. The `>` means this is still the same original source line, not a new line number. Each fragment is appended to the result. No character-limit truncation or first-N-lines selection is applied. Line endings and tabs are normalized for presentation, but the manifest hash is calculated from original file bytes rather than this display transformation.

Lines 71-109: `ExplanationDocument` and PDF Navigation

`ExplanationDocument` inherits ReportLab's `BaseDocTemplate`. Its constructor passes the output filename, A4 size, 19 mm left/right margins, 20 mm top margin, 19 mm bottom margin, descriptive PDF title/author, and compression setting to the base class. A body `Frame` fills the allowed document width/height. A default `PageTemplate` uses that frame and calls `decorate` on each page. The style dictionary is retained on the object and the heading counter starts at zero.

`beforeDocument` resets the counter each time a rendering pass begins. The table of contents requires multiple passes: the first discovers heading page numbers, and later passes lay out the resulting TOC and adjust pagination. Resetting yields stable bookmark identifiers across passes rather than continually increasing them.

`decorate` saves the canvas's graphics state before drawing. It sets a pale sand-colored stroke and draws a horizontal line 14 mm below the top. It sets muted text color and an 8-point Helvetica font, adds the reference title above the line, adds course/reference text at the bottom, and right-aligns the current page number. The saved state is restored so these choices cannot accidentally change a paragraph, diagram, or source listing drawn afterward. Dimensions are points internally; multiplying by mm converts the intended physical dimensions.

`afterFlowable` runs after a `Flowable` has been placed. A `Flowable` without `toc_level` is ordinary text and returns immediately. A numbered heading obtains a unique `section-N` key and a plain-text title. `bookmarkPage` binds that key to the current page. `addOutlineEntry` inserts a clickable PDF sidebar entry at chapter or subsection level; subsections start collapsed. `notify("TOCEntry", ...)` tells the TOC its level, title, page number, and bookmark destination. The counter is navigation state, not a source-code line counter.

Lines 112-131: `make_styles`, Typography

The renderer begins with ReportLab's standard sample stylesheet, then builds named styles rather than scattering font settings throughout parsing code. Body text is 9-point Helvetica with 13.5-point line spacing and six points after a paragraph; long words can split to avoid overflowing margins. A loop defines heading levels 1-4 with sizes 20, 13, 10.5, and 10. Each is bold, uses proportional line spacing, has space before/after, uses warm brown text, and remains with the next `Flowable` so headings do not sit alone at a page bottom.

Code samples use 6.5-point Courier with 8-point leading. Source appendices use 7.2-point Courier with 9-point leading, balancing very large retained libraries against readable monospaced references. Table cells inherit body behavior but use 7.8-point text and 10-point leading. The cover title uses 30-point size, 36-point leading, and centered alignment. A separate centered body style supports cover subtitles. The function returns the complete dictionary, making later style selection deterministic.

Lines 134-138: heading, Document Hierarchy

`heading(text, level, styles)` creates a Paragraph from escaped/formatted text. Levels deeper than four use the fourth visual style. Only levels one and two receive `toc_level`: level one becomes TOC/outline level zero, and level two becomes level one. This includes navigable chapter/subsection entries while keeping hundreds of small line-range headings out of the contents. The returned object is still a normal Paragraph with one additional navigation attribute.

Lines 141-206: markdown_flowables, Each Parsing Branch

The parser creates an output list, splits the chapter into lines, creates a pending prose buffer, and tracks a current index. Its nested `flush` function turns accumulated prose lines into a single escaped Paragraph separated by spaces, then clears the buffer. This preserves ordinary paragraphs spread across multiple editor lines. Flushing before structural blocks preserves their intended order.

The main loop strips whitespace only for syntax recognition; code blocks later use the original unstripped line. A line beginning with three backticks starts a literal code block. Pending prose is flushed, the opening marker skipped, and original code lines collected until a closing marker or end of file. They expand tabs and wrap at 109 characters with whitespace preserved. Chunks of at most 45 printed lines become Preformatted objects, reducing oversized unsplitable blocks. A small Spacer follows the code block. The language label after the opening marker is not used for syntax highlighting; this is a plain source-reference renderer.

A heading matched by one through six `#` characters followed by a space is split into marker and title. Its visual depth is capped at four and passed through `heading`. A Markdown table is recognized when a stripped line starts and ends with `|`. Consecutive pipe rows are collected; cells split on the separator and have surrounding whitespace removed. Separator rows consisting only of dashes and optional alignment colons are skipped, while real cells become formatted Paragraphs. This is a simple pipe-table subset: escaped literal pipes inside a cell are not a supported feature and should be written in prose/code blocks instead.

The table branch determines the largest cell count and pads shorter rows with empty cells so the table is rectangular. Available page width is divided evenly among columns. Header row repetition keeps column context on later pages. The header gets a pale sand background, all cells align at the top, a thin grid separates values, and top/bottom padding prevents cramped text. A Spacer separates the table from following content. The parser decreases its index once because the outer loop also advances it; without that correction the first non-table line would be skipped.

Lines beginning with `-`, `*`, or `+`, and lines matching a numbered-list marker, flush pending prose and become their own paragraphs. The markers remain visible text; the parser does not implement nested list indentation. Empty lines and simple horizontal separators flush prose. A `>` line becomes its own paragraph without the quotation marker; no special shaded quote box is generated. Everything else joins the pending buffer. After the loop, a final flush emits any trailing paragraph. The function returns the Flowables in original chapter order.

Lines 209-226: Arguments and Input Validation

`main` creates an `ArgumentParser` using the module description. `--output` accepts a Path and defaults to `docs/Arrakis_Code_Explanation.pdf`. Chapter and source Paths are joined beneath the known repository root. A list comprehension identifies inputs that are not files. If any are missing, `parser.error` prints the complete missing-input list and exits before generating a misleading partial document. A nonexistent output parent is also rejected; the tool does not create arbitrary external directory trees. An explicitly supplied relative output path is interpreted relative to the invoking shell, while default inputs and output remain repository-root based.

Lines 228-247: Cover, Contents, and Chapter Text

The generator creates styles and a Story list with an initial vertical spacer. The cover title uses explicit line breaks between Arrakis and Harvester Down. Subtitle paragraphs state the document's purpose, source-reference scope, and course. A UTC date records the documented snapshot's generation day. A page break starts Contents. The TOC has a bold 9-point chapter style and an 8-point indented subsection style. The TOC object joins the Story before any explanation chapters.

Each chapter then starts on a fresh page. Its UTF-8 text is parsed into Flowables and extended onto the Story. This makes chapter ordering explicit and does not require combining the editable Markdown files into another duplicate manual on disk. The Story is a sequence of rendering objects held in memory until the multi-pass build.

Lines 249-267: Snapshot Manifest and Source-Reference Rules

The manifest begins with UTC timestamp, empty source list, and empty chapter list. An appendix heading and introductory paragraph explain the exact line-number and continuation convention. They also distinguish authored explanations from third-party source reference and exclude installed external headers from the claimed repository scope.

For each source/configuration file, the generator reads its bytes, decodes UTF-8 while tolerating an initial byte-order mark, derives a repository-relative forward-slash path, counts physical text lines, and computes SHA-256 on the unchanged bytes. A dictionary records the path, count, and digest; a corresponding human-readable paragraph is added to the appendix. Hashing bytes detects changes in content and line endings, unlike merely checking file length. The SHA-256 value is an identity fingerprint, not evidence that the implementation is secure or correct.

Lines 269-286: Complete Source Appendices and PDF Verification

The source loop pairs each input Path with its manifest entry, begins a new page, and adds a navigable source-reference heading. `source_rows` formats every line of that file. Blocks of 72 printed rows become Preformatted Flowables; ReportLab can split them at page boundaries if necessary. The complete 95,000-plus-line miniaudio header is therefore retained, not cut down to the handful of calls the game makes.

Each explanation chapter is separately hashed and its whitespace-separated word count recorded. The custom document performs `multiBuild` with up to six layout passes so TOC page numbers stabilize. If layout or parsing fails, the exception remains visible instead of recording fabricated success. After successful PDF creation, `pypdf` reads the actual output and counts its pages. The manifest's PDF entry records the path, physical page count, and byte size. Outputs inside the repository use relative paths; an external requested destination is kept as an external path.

The manifest is serialized with two-space JSON indentation, UTF-8 encoding, and a terminal newline to `docs/documentation_manifest.json`. That generated JSON is not a source input to its own PDF, which would otherwise create a circular hash/size dependency. Two console messages report the actual PDF page/byte count and number of included source/configuration files and chapters. These counts confirm generation, not semantic completeness of the prose. The final `if __name__ == "__main__"` guard runs `main()` only when executing the script, allowing validation tools to import formatting helpers without regenerating the PDF.

How to Update and Validate the Manual

First update the explanation chapter corresponding to a behavior change, including code-range references if line numbers move. Add new project files to `SOURCE_PATHS` and new chapters to `CHAPTERS`. Then install the constrained dependencies and run the generator. Its strict input checks prevent accidental omission of already-listed files. Compare the manifest digests against repository files to verify that the PDF source snapshot is current. Use the PDF contents/sidebar to navigate explanation sections and source files rather than scrolling through thousands of vendor-reference pages.

The generator's subset parser handles the chapter conventions used here, not arbitrary Markdown extensions, Mermaid diagrams, remote image downloads, HTML execution, or syntax-highlighted code. Standard built-in fonts prioritize portability; unusual non-ASCII symbols should be written as words or ASCII formulas if a glyph is unavailable. Keeping

these limitations explicit avoids confusing presentation features with implemented game features.

Appendix A: Source Snapshot and Reading Rules

The following appendices contain every line of the retained application, tests, build/editor configuration, documentation generator, and vendored C/C++ sources. The left number is the physical source line, not a PDF line. A > continuation is the rest of that same source line; long lines are wrapped, never omitted. SHA-256 fingerprints identify this exact snapshot. Application semantics are explained in the preceding code-range chapters. The libraries are explained by functional families; their full source is included for reference, not presented as original game logic. Installed external GLFW, GLM and GLAD headers are dependencies, not files implemented in this repository.

12 | /*
13 | 1. Introduction
14 | =====
15 | To use miniaudio, just include "miniaudio.h" like any other header and add "miniaudio.c" to your
16 | source tree. If you don't want to add it to your source tree you can compile and link to it like
17 | any other library. Note that ABI compatibility is not guaranteed between versions, even with bug
18 | fix releases, so take care if compiling as a shared object.
19 |
20 | miniaudio includes both low level and high level APIs. The low level API is good for those who want
21 | to do all of their mixing themselves and only require a light weight interface to the underlying
22 | audio device. The high level API is good for those who have complex mixing and effect requirements.
23 |
24 | In miniaudio, objects are transparent structures. Unlike many other libraries, there are no handles
25 | to opaque objects which means you need to allocate memory for objects yourself. In the examples
26 | presented in this documentation you will often see objects declared on the stack. You need to be
27 | careful when translating these examples to your own code so that you don't accidentally declare
28 | your objects on the stack and then cause them to become invalid once the function returns. In
29 | addition, you must ensure the memory address of your objects remain the same throughout their
30 | lifetime. You therefore cannot be making copies of your objects.
31 |
32 | A config/init pattern is used throughout the entire library. The idea is that you set up a config
33 | object and pass that into the initialization routine. The advantage to this system is that the
34 | config object can be initialized with logical defaults and new properties added to it without
35 | breaking the API. The config object can be allocated on the stack and does not need to be
36 | maintained after initialization of the corresponding object.
37 |
38 |
39 | 1.1. Low Level API
40 | -----
41 | The low level API gives you access to the raw audio data of an audio device. It supports playback,
42 | capture, full-duplex and loopback (WASAPI only). You can enumerate over devices to determine which
43 | physical device(s) you want to connect to.
44 |
45 | The low level API uses the concept of a "device" as the abstraction for physical devices. The idea
46 | is that you choose a physical device to emit or capture audio from, and then move data to/from the
47 | device when miniaudio tells you to. Data is delivered to and from devices asynchronously via a
48 | callback which you specify when initializing the device.
49 |
50 | When initializing the device you first need to configure it. The device configuration allows you to
51 | specify things like the format of the data delivered via the callback, the size of the internal
52 | buffer and the ID of the device you want to emit or capture audio from.
53 |
54 | Once you have the device configuration set up you can initialize the device. When initializing a
55 | device you need to allocate memory for the device object beforehand. This gives the application
56 | complete control over how the memory is allocated. In the example below we initialize a playback
57 | device on the stack, but you could allocate it on the heap if that suits your situation better.
58 |
59 |     ``c
60 |     void data_callback(ma_device* pDevice, void* pOutput, const void* pInput, ma_uint32 frameCount)
61 |     {
62 |         // In playback mode copy data to pOutput. In capture mode read data from pInput. In
  > full-duplex mode, both
63 |         // pOutput and pInput will be valid and you can move data from pInput into pOutput. Never
  > process more than
64 |         // frameCount frames.
65 |     }
66 |
67 |     int main()
68 |     {
69 |         ma_device_config config = ma_device_config_init(ma_device_type_playback);
70 |         config.playback.format = ma_format_f32; // Set to ma_format_unknown to use the device's

```

```

> native format.
71 |         config.playback.channels = 2;                // Set to 0 to use the device's native channel
> count.
72 |         config.sampleRate        = 48000;            // Set to 0 to use the device's native sample
> rate.
73 |         config.dataCallback       = data_callback;    // This function will be called when miniaudio
> needs more data.
74 |         config.pUserData          = pMyCustomData;    // Can be accessed from the device object
> (device.pUserData).
75 |
76 |         ma_device device;
77 |         if (ma_device_init(NULL, &config, &device) != MA_SUCCESS) {
78 |             return -1; // Failed to initialize the device.
79 |         }
80 |
81 |         ma_device_start(&device);    // The device is sleeping by default so you'll need to start
> it manually.
82 |
83 |         // Do something here. Probably your program's main loop.
84 |
85 |         ma_device_uninit(&device);
86 |         return 0;
87 |     }
88 |     ...
89 |
90 | In the example above, `data_callback()` is where audio data is written and read from the device.
91 | The idea is in playback mode you cause sound to be emitted from the speakers by writing audio data
92 | to the output buffer (`pOutput` in the example). In capture mode you read data from the input
93 | buffer (`pInput`) to extract sound captured by the microphone. The `frameCount` parameter tells you
94 | how many frames can be written to the output buffer and read from the input buffer. A "frame" is
95 | one sample for each channel. For example, in a stereo stream (2 channels), one frame is 2
96 | samples: one for the left, one for the right. The channel count is defined by the device config.
97 | The size in bytes of an individual sample is defined by the sample format which is also specified
98 | in the device config. Multi-channel audio data is always interleaved, which means the samples for
99 | each frame are stored next to each other in memory. For example, in a stereo stream the first pair
100 | of samples will be the left and right samples for the first frame, the second pair of samples will
101 | be the left and right samples for the second frame, etc.
102 |
103 | The configuration of the device is defined by the `ma_device_config` structure. The config object
104 | is always initialized with `ma_device_config_init()`. It's important to always initialize the
105 | config with this function as it initializes it with logical defaults and ensures your program
106 | doesn't break when new members are added to the `ma_device_config` structure. The example above
107 | uses a fairly simple and standard device configuration. The call to `ma_device_config_init()` takes
108 | a single parameter, which is whether or not the device is a playback, capture, duplex or loopback
109 | device (loopback devices are not supported on all backends). The `config.playback.format` member
110 | sets the sample format which can be one of the following (all formats are native-endian):
111 |
112 | +-----+-----+-----+-----+
113 | | Symbol      | Description                               | Range                |
114 | +-----+-----+-----+-----+
115 | | ma_format_f32 | 32-bit floating point                     | [-1, 1]              |
116 | | ma_format_s16 | 16-bit signed integer                     | [-32768, 32767]      |
117 | | ma_format_s24 | 24-bit signed integer (tightly packed)    | [-8388608, 8388607]  |
118 | | ma_format_s32 | 32-bit signed integer                     | [-2147483648, 2147483647] |
119 | | ma_format_u8  | 8-bit unsigned integer                    | [0, 255]             |
120 | +-----+-----+-----+-----+
121 |
122 | The `config.playback.channels` member sets the number of channels to use with the device. The
123 | channel count cannot exceed MA_MAX_CHANNELS. The `config.sampleRate` member sets the sample rate
124 | (which must be the same for both playback and capture in full-duplex configurations). This is
125 | usually set to 44100 or 48000, but can be set to anything. It's recommended to keep this between
126 | 8000 and 384000, however.
127 |
128 | Note that leaving the format, channel count and/or sample rate at their default values will result
129 | in the internal device's native configuration being used which is useful if you want to avoid the
130 | overhead of miniaudio's automatic data conversion.
131 |
132 | In addition to the sample format, channel count and sample rate, the data callback and user data
133 | pointer are also set via the config. The user data pointer is not passed into the callback as a
134 | parameter, but is instead set to the `pUserData` member of `ma_device` which you can access
135 | directly since all miniaudio structures are transparent.
136 |
137 | Initializing the device is done with `ma_device_init()`. This will return a result code telling you
138 | what went wrong, if anything. On success it will return `MA_SUCCESS`. After initialization is
139 | complete the device will be in a stopped state. To start it, use `ma_device_start()`.
140 | Uninitializing the device will stop it, which is what the example above does, but you can also stop
141 | the device with `ma_device_stop()`. To resume the device simply call `ma_device_start()` again.
142 | Note that it's important to never stop or start the device from inside the callback. This will
143 | result in a deadlock. Instead you set a variable or signal an event indicating that the device

```

```

144 | needs to stop and handle it in a different thread. The following APIs must never be called inside
145 | the callback:
146 |
147 |     ``c
148 |     ma_device_init()
149 |     ma_device_init_ex()
150 |     ma_device_uninit()
151 |     ma_device_start()
152 |     ma_device_stop()
153 |     ``
154 |
155 | You must never try uninitialized and reinitializing a device inside the callback. You must also
156 | never try to stop and start it from inside the callback. There are a few other things you shouldn't
157 | do in the callback depending on your requirements, however this isn't so much a thread-safety
158 | thing, but rather a real-time processing thing which is beyond the scope of this introduction.
159 |
160 | The example above demonstrates the initialization of a playback device, but it works exactly the
161 | same for capture. All you need to do is change the device type from `ma_device_type_playback` to
162 | `ma_device_type_capture` when setting up the config, like so:
163 |
164 |     ``c
165 |     ma_device_config config = ma_device_config_init(ma_device_type_capture);
166 |     config.capture.format    = MY_FORMAT;
167 |     config.capture.channels  = MY_CHANNEL_COUNT;
168 |     ``
169 |
170 | In the data callback you just read from the input buffer (`pInput` in the example above) and leave
171 | the output buffer alone (it will be set to NULL when the device type is set to
172 | `ma_device_type_capture`).
173 |
174 | These are the available device types and how you should handle the buffers in the callback:
175 |
176 | +-----+-----+-----+
177 | | Device Type          | | Callback Behavior          | |
178 | +-----+-----+-----+
179 | | ma_device_type_playback | | Write to output buffer, leave input buffer untouched. | |
180 | | ma_device_type_capture  | | Read from input buffer, leave output buffer untouched. | |
181 | | ma_device_type_duplex   | | Read from input buffer, write to output buffer.         | |
182 | | ma_device_type_loopback | | Read from input buffer, leave output buffer untouched. | |
183 | +-----+-----+-----+
184 |
185 | You will notice in the example above that the sample format and channel count is specified
186 | separately for playback and capture. This is to support different data formats between the playback
187 | and capture devices in a full-duplex system. An example may be that you want to capture audio data
188 | as a monaural stream (one channel), but output sound to a stereo speaker system. Note that if you
189 | use different formats between playback and capture in a full-duplex configuration you will need to
190 | convert the data yourself. There are functions available to help you do this which will be
191 | explained later.
192 |
193 | The example above did not specify a physical device to connect to which means it will use the
194 | operating system's default device. If you have multiple physical devices connected and you want to
195 | use a specific one you will need to specify the device ID in the configuration, like so:
196 |
197 |     ``c
198 |     config.playback.pDeviceID = pMyPlaybackDeviceID;    // Only if requesting a playback or duplex
199 |     config.capture.pDeviceID  = pMyCaptureDeviceID;     // Only if requesting a capture, duplex or
200 |     ``
201 |
202 | To retrieve the device ID you will need to perform device enumeration, however this requires the
203 | use of a new concept called the "context". Conceptually speaking the context sits above the device.
204 | There is one context to many devices. The purpose of the context is to represent the backend at a
205 | more global level and to perform operations outside the scope of an individual device. Mainly it is
206 | used for performing run-time linking against backend libraries, initializing backends and
207 | enumerating devices. The example below shows how to enumerate devices.
208 |
209 |     ``c
210 |     ma_context context;
211 |     if (ma_context_init(NULL, 0, NULL, &context) != MA_SUCCESS) {
212 |         // Error.
213 |     }
214 |
215 |     ma_device_info* pPlaybackInfos;
216 |     ma_uint32 playbackCount;
217 |     ma_device_info* pCaptureInfos;
218 |     ma_uint32 captureCount;
219 |     if (ma_context_get_devices(&context, &pPlaybackInfos, &playbackCount, &pCaptureInfos,
220 | > &captureCount) != MA_SUCCESS) {

```

```

220 |         // Error.
221 |     }
222 |
223 |     // Loop over each device info and do something with it. Here we just print the name with their
> index. You may want
224 |     // to give the user the opportunity to choose which device they'd prefer.
225 |     for (ma_uint32 iDevice = 0; iDevice < playbackCount; iDevice += 1) {
226 |         printf("%d - %s\n", iDevice, pPlaybackInfos[iDevice].name);
227 |     }
228 |
229 |     ma_device_config config = ma_device_config_init(ma_device_type_playback);
230 |     config.playback.pDeviceID = &pPlaybackInfos[chosenPlaybackDeviceIndex].id;
231 |     config.playback.format      = MY_FORMAT;
232 |     config.playback.channels    = MY_CHANNEL_COUNT;
233 |     config.sampleRate          = MY_SAMPLE_RATE;
234 |     config.dataCallback         = data_callback;
235 |     config.pUserData            = pMyCustomData;
236 |
237 |     ma_device device;
238 |     if (ma_device_init(&context, &config, &device) != MA_SUCCESS) {
239 |         // Error
240 |     }
241 |
242 |     ...
243 |
244 |     ma_device_uninit(&device);
245 |     ma_context_uninit(&context);
246 |     ```
247 |
248 | The first thing we do in this example is initialize a `ma_context` object with `ma_context_init()`.
249 | The first parameter is a pointer to a list of `ma_backend` values which are used to override the
250 | default backend priorities. When this is NULL, as in this example, miniaudio's default priorities
251 | are used. The second parameter is the number of backends listed in the array pointed to by the
252 | first parameter. The third parameter is a pointer to a `ma_context_config` object which can be
253 | NULL, in which case defaults are used. The context configuration is used for setting the logging
254 | callback, custom memory allocation callbacks, user-defined data and some backend-specific
255 | configurations.
256 |
257 | Once the context has been initialized you can enumerate devices. In the example above we use the
258 | simpler `ma_context_get_devices()`, however you can also use a callback for handling devices by
259 | using `ma_context_enumerate_devices()`. When using `ma_context_get_devices()` you provide a pointer
260 | to a pointer that will, upon output, be set to a pointer to a buffer containing a list of
261 | `ma_device_info` structures. You also provide a pointer to an unsigned integer that will receive
262 | the number of items in the returned buffer. Do not free the returned buffers as their memory is
263 | managed internally by miniaudio.
264 |
265 | The `ma_device_info` structure contains an `id` member which is the ID you pass to the device
266 | config. It also contains the name of the device which is useful for presenting a list of devices
267 | to the user via the UI.
268 |
269 | When creating your own context you will want to pass it to `ma_device_init()` when initializing the
270 | device. Passing in NULL, like we do in the first example, will result in miniaudio creating the
271 | context for you, which you don't want to do since you've already created a context. Note that
272 | internally the context is only tracked by it's pointer which means you must not change the location
273 | of the `ma_context` object. If this is an issue, consider using `malloc()` to allocate memory for
274 | the context.
275 |
276 |
277 | 1.2. High Level API
278 | -----
279 | The high level API consists of three main parts:
280 |
281 | * Resource management for loading and streaming sounds.
282 | * A node graph for advanced mixing and effect processing.
283 | * A high level "engine" that wraps around the resource manager and node graph.
284 |
285 | The resource manager (`ma_resource_manager`) is used for loading sounds. It supports loading sounds
286 | fully into memory and also streaming. It will also deal with reference counting for you which
287 | avoids the same sound being loaded multiple times.
288 |
289 | The node graph is used for mixing and effect processing. The idea is that you connect a number of
290 | nodes into the graph by connecting each node's outputs to another node's inputs. Each node can
291 | implement its own effect. By chaining nodes together, advanced mixing and effect processing can
292 | be achieved.
293 |
294 | The engine encapsulates both the resource manager and the node graph to create a simple, easy to
295 | use high level API. The resource manager and node graph APIs are covered in more later sections of
296 | this manual.
297 |

```

```

298 | The code below shows how you can initialize an engine using its default configuration.
299 |
300 |     ``c
301 |     ma_result result;
302 |     ma_engine engine;
303 |
304 |     result = ma_engine_init(NULL, &engine);
305 |     if (result != MA_SUCCESS) {
306 |         return result; // Failed to initialize the engine.
307 |     }
308 |     ...
309 |
310 | This creates an engine instance which will initialize a device internally which you can access with
311 | `ma_engine_get_device()`. It will also initialize a resource manager for you which can be accessed
312 | with `ma_engine_get_resource_manager()`. The engine itself is a node graph (`ma_node_graph`) which
313 | means you can pass a pointer to the engine object into any of the `ma_node_graph` APIs (with a
314 | cast). Alternatively, you can use `ma_engine_get_node_graph()` instead of a cast.
315 |
316 | Note that all objects in miniaudio, including the `ma_engine` object in the example above, are
317 | transparent structures. There are no handles to opaque structures in miniaudio which means you need
318 | to be mindful of how you declare them. In the example above we are declaring it on the stack, but
319 | this will result in the struct being invalidated once the function encapsulating it returns. If
320 | allocating the engine on the heap is more appropriate, you can easily do so with a standard call
321 | to `malloc()` or whatever heap allocation routine you like:
322 |
323 |     ``c
324 |     ma_engine* pEngine = malloc(sizeof(*pEngine));
325 |     ...
326 |
327 | The `ma_engine` API uses the same config/init pattern used all throughout miniaudio. To configure
328 | an engine, you can fill out a `ma_engine_config` object and pass it into the first parameter of
329 | `ma_engine_init()`:
330 |
331 |     ``c
332 |     ma_result result;
333 |     ma_engine engine;
334 |     ma_engine_config engineConfig;
335 |
336 |     engineConfig = ma_engine_config_init();
337 |     engineConfig.pResourceManager = &myCustomResourceManager; // <-- Initialized as some earlier
> stage.
338 |
339 |     result = ma_engine_init(&engineConfig, &engine);
340 |     if (result != MA_SUCCESS) {
341 |         return result;
342 |     }
343 |     ...
344 |
345 | This creates an engine instance using a custom config. In this particular example it's showing how
346 | you can specify a custom resource manager rather than having the engine initialize one internally.
347 | This is particularly useful if you want to have multiple engine's share the same resource manager.
348 |
349 | The engine must be uninitialized with `ma_engine_uninit()` when it's no longer needed.
350 |
351 | By default the engine will be started, but nothing will be playing because no sounds have been
352 | initialized. The easiest but least flexible way of playing a sound is like so:
353 |
354 |     ``c
355 |     ma_engine_play_sound(&engine, "my_sound.wav", NULL);
356 |     ...
357 |
358 | This plays what miniaudio calls an "inline" sound. It plays the sound once, and then puts the
359 | internal sound up for recycling. The last parameter is used to specify which sound group the sound
360 | should be associated with which will be explained later. This particular way of playing a sound is
361 | simple, but lacks flexibility and features. A more flexible way of playing a sound is to first
362 | initialize a sound:
363 |
364 |     ``c
365 |     ma_result result;
366 |     ma_sound sound;
367 |
368 |     result = ma_sound_init_from_file(&engine, "my_sound.wav", 0, NULL, NULL, &sound);
369 |     if (result != MA_SUCCESS) {
370 |         return result;
371 |     }
372 |
373 |     ma_sound_start(&sound);
374 |     ...
375 |

```

```

376 | This returns a `ma_sound` object which represents a single instance of the specified sound file. If
377 | you want to play the same file multiple times simultaneously, you need to create one sound for each
378 | instance.
379 |
380 | Sounds should be uninitialized with `ma_sound_uninit()`.
381 |
382 | Sounds are not started by default. Start a sound with `ma_sound_start()` and stop it with
383 | `ma_sound_stop()`. When a sound is stopped, it is not rewound to the start. Use
384 | `ma_sound_seek_to_pcm_frame(&sound, 0)` to seek back to the start of a sound. By default, starting
385 | and stopping sounds happens immediately, but sometimes it might be convenient to schedule the sound
386 | to be started and/or stopped at a specific time. This can be done with the following functions:
387 |
388 |     ```c
389 |     ma_sound_set_start_time_in_pcm_frames()
390 |     ma_sound_set_start_time_in_milliseconds()
391 |     ma_sound_set_stop_time_in_pcm_frames()
392 |     ma_sound_set_stop_time_in_milliseconds()
393 |     ```
394 |
395 | The start/stop time needs to be specified based on the absolute timer which is controlled by the
396 | engine. The current global time in PCM frames can be retrieved with
397 | `ma_engine_get_time_in_pcm_frames()`. The engine's global time can be changed with
398 | `ma_engine_set_time_in_pcm_frames()` for synchronization purposes if required. Note that scheduling
399 | a start time still requires an explicit call to `ma_sound_start()` before anything will play:
400 |
401 |     ```c
402 |     ma_sound_set_start_time_in_pcm_frames(&sound, ma_engine_get_time_in_pcm_frames(&engine) +
> (ma_engine_get_sample_rate(&engine) * 2);
403 |     ma_sound_start(&sound);
404 |     ```
405 |
406 | The third parameter of `ma_sound_init_from_file()` is a set of flags that control how the sound be
407 | loaded and a few options on which features should be enabled for that sound. By default, the sound
408 | is synchronously loaded fully into memory straight from the file system without any kind of
409 | decoding. If you want to decode the sound before storing it in memory, you need to specify the
410 | `MA_SOUND_FLAG_DECODE` flag. This is useful if you want to incur the cost of decoding at an earlier
411 | stage, such as a loading stage. Without this option, decoding will happen dynamically at mixing
412 | time which might be too expensive on the audio thread.
413 |
414 | If you want to load the sound asynchronously, you can specify the `MA_SOUND_FLAG_ASYNC` flag. This
415 | will result in `ma_sound_init_from_file()` returning quickly, but the sound will not start playing
416 | until the sound has had some audio decoded.
417 |
418 | The fourth parameter is a pointer to sound group. A sound group is used as a mechanism to organise
419 | sounds into groups which have their own effect processing and volume control. An example is a game
420 | which might have separate groups for sfx, voice and music. Each of these groups have their own
421 | independent volume control. Use `ma_sound_group_init()` or `ma_sound_group_init_ex()` to initialize
422 | a sound group.
423 |
424 | Sounds and sound groups are nodes in the engine's node graph and can be plugged into any `ma_node`
425 | API. This makes it possible to connect sounds and sound groups to effect nodes to produce complex
426 | effect chains.
427 |
428 | A sound can have its volume changed with `ma_sound_set_volume()`. If you prefer decibel volume
429 | control you can use `ma_volume_db_to_linear()` to convert from decibel representation to linear.
430 |
431 | Panning and pitching is supported with `ma_sound_set_pan()` and `ma_sound_set_pitch()`. If you know
432 | a sound will never have its pitch changed with `ma_sound_set_pitch()` or via the doppler effect,
433 | you can specify the `MA_SOUND_FLAG_NO_PITCH` flag when initializing the sound for an optimization.
434 |
435 | By default, sounds and sound groups have spatialization enabled. If you don't ever want to
436 | spatialize your sounds, initialize the sound with the `MA_SOUND_FLAG_NO_SPATIALIZATION` flag. The
437 | spatialization model is fairly simple and is roughly on feature parity with OpenAL. HRTF and
438 | environmental occlusion are not currently supported, but planned for the future. The supported
439 | features include:
440 |
441 |     * Sound and listener positioning and orientation with cones
442 |     * Attenuation models: none, inverse, linear and exponential
443 |     * Doppler effect
444 |
445 | Sounds can be faded in and out with `ma_sound_set_fade_in_pcm_frames()`.
446 |
447 | To check if a sound is currently playing, you can use `ma_sound_is_playing()`. To check if a sound
448 | is at the end, use `ma_sound_at_end()`. Looping of a sound can be controlled with
449 | `ma_sound_set_looping()`. Use `ma_sound_is_looping()` to check whether or not the sound is looping.
450 |
451 |
452 |
453 | 2. Building

```

```

454 | =====
455 | miniaudio should work cleanly out of the box without the need to download or install any
456 | dependencies. See below for platform-specific details.
457 |
458 | This library has been designed to be added directly to your source tree which is the preferred way
459 | of using it, but you can compile it as a normal library if that's your preference. Be careful if
460 | compiling as a shared object because miniaudio is not ABI compatible between any release, including
461 | bug fix releases. It's recommended you link statically.
462 |
463 | Note that GCC and Clang require `-msse2`, `-mavx2`, etc. for SIMD optimizations.
464 |
465 | If you get errors about undefined references to `__sync_val_compare_and_swap_8`, `__atomic_load_8`,
466 | etc. you need to link with `-latomic`.
467 |
468 |
469 | 2.1. Windows
470 | -----
471 | The Windows build should compile cleanly on all popular compilers without the need to configure any
472 | include paths nor link to any libraries.
473 |
474 | The UWP build may require linking to mmdevapi.lib if you get errors about an unresolved external
475 | symbol for `ActivateAudioInterfaceAsync()`.
476 |
477 |
478 | 2.2. macOS and iOS
479 | -----
480 | The macOS build should compile cleanly without the need to download any dependencies nor link to
481 | any libraries or frameworks. The iOS build needs to be compiled as Objective-C and will need to
482 | link the relevant frameworks but should compile cleanly out of the box with Xcode. Compiling
483 | through the command line requires linking to `-lpthread` and `-lm`.
484 |
485 | Due to the way miniaudio links to frameworks at runtime, your application may not pass Apple's
486 | notarization process. To fix this there are two options. The first is to compile with
487 | `-DMA_NO_RUNTIME_LINKING` which in turn will require linking with
488 | `-framework CoreFoundation -framework CoreAudio -framework AudioToolbox`. If you get errors about
489 | AudioToolbox, try with `-framework AudioUnit` instead. You may get this when using older versions
490 | of iOS. Alternatively, if you would rather keep using runtime linking you can add the following to
491 | your entitlements.xcent file:
492 |
493 |     <key>com.apple.security.cs.allow-dyld-environment-variables</key>
494 |     <true/>
495 |     <key>com.apple.security.cs.allow-unsigned-executable-memory</key>
496 |     <true/>
497 |
498 |
499 | See this discussion for more info: https://github.com/mackron/miniaudio/issues/203.
500 |
501 |
502 |
503 | 2.3. Linux
504 | -----
505 | The Linux build only requires linking to `-ldl`, `-lpthread` and `-lm`. You do not need any
506 | development packages. You may need to link with `-latomic` if you're compiling for 32-bit ARM.
507 |
508 |
509 | 2.4. BSD
510 | -----
511 | The BSD build only requires linking to `-lpthread` and `-lm`. NetBSD uses audio(4), OpenBSD uses
512 | sndio and FreeBSD uses OSS. You may need to link with `-latomic` if you're compiling for 32-bit
513 | ARM.
514 |
515 |
516 | 2.5. Android
517 | -----
518 | AAudio is the highest priority backend on Android. This should work out of the box without needing
519 | any kind of compiler configuration. Support for AAudio starts with Android 8 which means older
520 | versions will fall back to OpenSL|ES which requires API level 16+.
521 |
522 | There have been reports that the OpenSL|ES backend fails to initialize on some Android based
523 | devices due to `dlopen()` failing to open "libOpenSLES.so". If this happens on your platform
524 | you'll need to disable run-time linking with `MA_NO_RUNTIME_LINKING` and link with -lOpenSLES.
525 |
526 |
527 | 2.6. Emscripten
528 | -----
529 | The Emscripten build emits Web Audio JavaScript directly and should compile cleanly out of the box.
530 | You cannot use `-std=c*` compiler flags, nor `-ansi`.
531 |
532 | You can enable the use of AudioWorklets by defining `MA_ENABLE_AUDIO_WORKLETS` and then compiling

```

```

533 | with the following options:
534 |
535 |     -sAUDIO_WORKLET=1 -sWASM_WORKERS=1 -sASYNCIFY
536 |
537 | An example for compiling with AudioWorklet support might look like this:
538 |
539 |     emcc program.c -o bin/program.html -DMA_ENABLE_AUDIO_WORKLETS -sAUDIO_WORKLET=1 -sWASM_WORKERS=1
540 | > -sASYNCIFY
541 |
542 | To run locally, you'll need to use emrun:
543 |
544 |     emrun bin/program.html
545 |
546 |
547 | 2.7. Build Options
548 | -----
549 | `#define` these options before including miniaudio.c, or pass them as compiler flags:
550 |
551 | +-----+-----+-----+
552 | | Option                                | Description |
553 | +-----+-----+-----+
554 | | MA_NO_WASAPI                         | Disables the WASAPI backend. |
555 | +-----+-----+-----+
556 | | MA_NO_DSOUND                         | Disables the DirectSound backend. |
557 | +-----+-----+-----+
558 | | MA_NO_WINMM                         | Disables the WinMM backend. |
559 | +-----+-----+-----+
560 | | MA_NO_ALSA                         | Disables the ALSA backend. |
561 | +-----+-----+-----+
562 | | MA_NO_PULSEAUDIO                   | Disables the PulseAudio backend. |
563 | +-----+-----+-----+
564 | | MA_NO_JACK                         | Disables the JACK backend. |
565 | +-----+-----+-----+
566 | | MA_NO_COREAUDIO                   | Disables the Core Audio backend. |
567 | +-----+-----+-----+
568 | | MA_NO_SNDIO                       | Disables the sndio backend. |
569 | +-----+-----+-----+
570 | | MA_NO_AUDIO4                       | Disables the audio(4) backend. |
571 | +-----+-----+-----+
572 | | MA_NO_OSS                         | Disables the OSS backend. |
573 | +-----+-----+-----+
574 | | MA_NO_AAUDIO                       | Disables the AAudio backend. |
575 | +-----+-----+-----+
576 | | MA_NO_OPENSLE                      | Disables the OpenSLES backend. |
577 | +-----+-----+-----+
578 | | MA_NO_WEBAUDIO                     | Disables the Web Audio backend. |
579 | +-----+-----+-----+
580 | | MA_NO_CUSTOM                       | Disables support for custom backends. |
581 | +-----+-----+-----+

```

```

719 |
720 | 3. Definitions
721 | =====
722 | This section defines common terms used throughout miniaudio. Unfortunately there is often ambiguity
723 | in the use of terms throughout the audio space, so this section is intended to clarify how miniaudio
724 | uses each term.
725 |
726 | 3.1. Sample
727 | -----
728 | A sample is a single unit of audio data. If the sample format is f32, then one sample is one 32-bit
729 | floating point number.
730 |
731 | 3.2. Frame / PCM Frame
732 | -----
733 | A frame is a group of samples equal to the number of channels. For a stereo stream a frame is 2
734 | samples, a mono frame is 1 sample, a 5.1 surround sound frame is 6 samples, etc. The terms "frame"
735 | and "PCM frame" are the same thing in miniaudio. Note that this is different to a compressed frame.
736 | If ever miniaudio needs to refer to a compressed frame, such as a FLAC frame, it will always
737 | clarify what it's referring to with something like "FLAC frame".
738 |
739 | 3.3. Channel
740 | -----
741 | A stream of monaural audio that is emitted from an individual speaker in a speaker system, or
742 | received from an individual microphone in a microphone system. A stereo stream has two channels (a
743 | left channel, and a right channel), a 5.1 surround sound system has 6 channels, etc. Some audio
744 | systems refer to a channel as a complex audio stream that's mixed with other channels to produce
745 | the final mix - this is completely different to miniaudio's use of the term "channel" and should
746 | not be confused.
747 |
748 | 3.4. Sample Rate
749 | -----
750 | The sample rate in miniaudio is always expressed in Hz, such as 44100, 48000, etc. It's the number
751 | of PCM frames that are processed per second.
752 |
753 | 3.5. Formats
754 | -----
755 | Throughout miniaudio you will see references to different sample formats:
756 |
757 | +-----+-----+-----+-----+-----+-----+
758 | | Symbol          | Description                               | Range                               |
759 | +-----+-----+-----+-----+-----+-----+

```

```

760 | | ma_format_f32 | 32-bit floating point | [-1, 1] |
761 | | ma_format_s16 | 16-bit signed integer | [-32768, 32767] |
762 | | ma_format_s24 | 24-bit signed integer (tightly packed) | [-8388608, 8388607] |
763 | | ma_format_s32 | 32-bit signed integer | [-2147483648, 2147483647] |
764 | | ma_format_u8 | 8-bit unsigned integer | [0, 255] |
765 | +-----+-----+-----+-----+-----+-----+
766 |
767 | All formats are native-endian.
768 |
769 |
770 |
771 | 4. Data Sources
772 | =====
773 | The data source abstraction in miniaudio is used for retrieving audio data from some source. A few
774 | examples include `ma_decoder`, `ma_noise` and `ma_waveform`. You will need to be familiar with data
775 | sources in order to make sense of some of the higher level concepts in miniaudio.
776 |
777 | The `ma_data_source` API is a generic interface for reading from a data source. Any object that
778 | implements the data source interface can be plugged into any `ma_data_source` function.
779 |
780 | To read data from a data source:
781 |
782 | ```c
783 |     ma_result result;
784 |     ma_uint64 framesRead;
785 |
786 |     result = ma_data_source_read_pcm_frames(pDataSource, pFramesOut, frameCount, &framesRead);
787 |     if (result != MA_SUCCESS) {
788 |         return result; // Failed to read data from the data source.
789 |     }
790 |     ...
791 |
792 | If you don't need the number of frames that were successfully read you can pass in `NULL` to the
793 | `pFramesRead` parameter. If this returns a value less than the number of frames requested it means
794 | the end of the file has been reached. `MA_AT_END` will be returned only when the number of frames
795 | read is 0.
796 |
797 | When calling any data source function, with the exception of `ma_data_source_init()` and
798 | `ma_data_source_uninit()`, you can pass in any object that implements a data source. For example,
799 | you could plug in a decoder like so:
800 |
801 | ```c
802 |     ma_result result;
803 |     ma_uint64 framesRead;
804 |     ma_decoder decoder; // <-- This would be initialized with `ma_decoder_init_*()``.
805 |
806 |     result = ma_data_source_read_pcm_frames(&decoder, pFramesOut, frameCount, &framesRead);
807 |     if (result != MA_SUCCESS) {
808 |         return result; // Failed to read data from the decoder.
809 |     }
810 |     ...
811 |
812 | If you want to seek forward you can pass in `NULL` to the `pFramesOut` parameter. Alternatively you
813 | can use `ma_data_source_seek_pcm_frames()`.
814 |
815 | To seek to a specific PCM frame:
816 |
817 | ```c
818 |     result = ma_data_source_seek_to_pcm_frame(pDataSource, frameIndex);
819 |     if (result != MA_SUCCESS) {
820 |         return result; // Failed to seek to PCM frame.
821 |     }
822 |     ...
823 |
824 | You can retrieve the total length of a data source in PCM frames, but note that some data sources
825 | may not have the notion of a length, such as noise and waveforms, and others may just not have a
826 | way of determining the length such as some decoders. To retrieve the length:
827 |
828 | ```c
829 |     ma_uint64 length;
830 |
831 |     result = ma_data_source_get_length_in_pcm_frames(pDataSource, &length);
832 |     if (result != MA_SUCCESS) {
833 |         return result; // Failed to retrieve the length.
834 |     }
835 |     ...
836 |
837 | Care should be taken when retrieving the length of a data source where the underlying decoder is
838 | pulling data from a data stream with an undefined length, such as internet radio or some kind of

```

```

839 | broadcast. If you do this, `ma_data_source_get_length_in_pcm_frames()` may never return.
840 |
841 | The current position of the cursor in PCM frames can also be retrieved:
842 |
843 |     ```c
844 |     ma_uint64 cursor;
845 |
846 |     result = ma_data_source_get_cursor_in_pcm_frames(pDataSource, &cursor);
847 |     if (result != MA_SUCCESS) {
848 |         return result; // Failed to retrieve the cursor.
849 |     }
850 |     ...
851 |
852 | You will often need to know the data format that will be returned after reading. This can be
853 | retrieved like so:
854 |
855 |     ```c
856 |     ma_format format;
857 |     ma_uint32 channels;
858 |     ma_uint32 sampleRate;
859 |     ma_channel channelMap[MA_MAX_CHANNELS];
860 |
861 |     result = ma_data_source_get_data_format(pDataSource, &format, &channels, &sampleRate,
> channelMap, MA_MAX_CHANNELS);
862 |     if (result != MA_SUCCESS) {
863 |         return result; // Failed to retrieve data format.
864 |     }
865 |     ...
866 |
867 | If you do not need a specific data format property, just pass in NULL to the respective parameter.
868 |
869 | There may be cases where you want to implement something like a sound bank where you only want to
870 | read data within a certain range of the underlying data. To do this you can use a range:
871 |
872 |     ```c
873 |     result = ma_data_source_set_range_in_pcm_frames(pDataSource, rangeBegInFrames,
> rangeEndInFrames);
874 |     if (result != MA_SUCCESS) {
875 |         return result; // Failed to set the range.
876 |     }
877 |     ...
878 |
879 | This is useful if you have a sound bank where many sounds are stored in the same file and you want
880 | the data source to only play one of those sub-sounds. Note that once the range is set, everything
881 | that takes a position, such as cursors and loop points, should always be relative to the start of
882 | the range. When the range is set, any previously defined loop point will be reset.
883 |
884 | Custom loop points can also be used with data sources. By default, data sources will loop after
885 | they reach the end of the data source, but if you need to loop at a specific location, you can do
886 | the following:
887 |
888 |     ```c
889 |     result = ma_data_source_set_loop_point_in_pcm_frames(pDataSource, loopBegInFrames,
> loopEndInFrames);
890 |     if (result != MA_SUCCESS) {
891 |         return result; // Failed to set the loop point.
892 |     }
893 |     ...
894 |
895 | The loop point is relative to the current range.
896 |
897 | It's sometimes useful to chain data sources together so that a seamless transition can be achieved.
898 | To do this, you can use chaining:
899 |
900 |     ```c
901 |     ma_decoder decoder1;
902 |     ma_decoder decoder2;
903 |
904 |     // ... initialize decoders with ma_decoder_init_*() ...
905 |
906 |     result = ma_data_source_set_next(&decoder1, &decoder2);
907 |     if (result != MA_SUCCESS) {
908 |         return result; // Failed to set the next data source.
909 |     }
910 |
911 |     result = ma_data_source_read_pcm_frames(&decoder1, pFramesOut, frameCount, pFramesRead);
912 |     if (result != MA_SUCCESS) {
913 |         return result; // Failed to read from the decoder.
914 |     }

```

```

915 |     ...
916 |
917 | In the example above we're using decoders. When reading from a chain, you always want to read from
918 | the top level data source in the chain. In the example above, `decoder1` is the top level data
919 | source in the chain. When `decoder1` reaches the end, `decoder2` will start seamlessly without any
920 | gaps.
921 |
922 | Note that when looping is enabled, only the current data source will be looped. You can loop the
923 | entire chain by linking in a loop like so:
924 |
925 |     ...c
926 |     ma_data_source_set_next(&decoder1, &decoder2); // decoder1 -> decoder2
927 |     ma_data_source_set_next(&decoder2, &decoder1); // decoder2 -> decoder1 (loop back to the
> start).
928 |     ...
929 |
930 | Note that setting up chaining is not thread safe, so care needs to be taken if you're dynamically
931 | changing links while the audio thread is in the middle of reading.
932 |
933 | Do not use `ma_decoder_seek_to_pcm_frame()` as a means to reuse a data source to play multiple
934 | instances of the same sound simultaneously. This can be extremely inefficient depending on the type
935 | of data source and can result in glitching due to subtle changes to the state of internal filters.
936 | Instead, initialize multiple data sources for each instance.
937 |
938 |
939 | 4.1. Custom Data Sources
940 | -----
941 | You can implement a custom data source by implementing the functions in `ma_data_source_vtable`.
942 | Your custom object must have `ma_data_source_base` as it's first member:
943 |
944 |     ...c
945 |     struct my_data_source
946 |     {
947 |         ma_data_source_base base;
948 |         ...
949 |     };
950 |     ...
951 |
952 | In your initialization routine, you need to call `ma_data_source_init()` in order to set up the
953 | base object (`ma_data_source_base`):
954 |
955 |     ...c
956 |     static ma_result my_data_source_read(ma_data_source* pDataSource, void* pFramesOut, ma_uint64
> frameCount, ma_uint64* pFramesRead)
957 |     {
958 |         // Read data here. Output in the same format returned by my_data_source_get_data_format().
959 |     }
960 |
961 |     static ma_result my_data_source_seek(ma_data_source* pDataSource, ma_uint64 frameIndex)
962 |     {
963 |         // Seek to a specific PCM frame here. Return MA_NOT_IMPLEMENTED if seeking is not supported.
964 |     }
965 |
966 |     static ma_result my_data_source_get_data_format(ma_data_source* pDataSource, ma_format* pFormat,
> ma_uint32* pChannels, ma_uint32* pSampleRate, ma_channel* pChannelMap, size_t channelMapCap)
967 |     {
968 |         // Return the format of the data here.
969 |     }
970 |
971 |     static ma_result my_data_source_get_cursor(ma_data_source* pDataSource, ma_uint64* pCursor)
972 |     {
973 |         // Retrieve the current position of the cursor here. Return MA_NOT_IMPLEMENTED and set
> *pCursor to 0 if there is no notion of a cursor.
974 |     }
975 |
976 |     static ma_result my_data_source_get_length(ma_data_source* pDataSource, ma_uint64* pLength)
977 |     {
978 |         // Retrieve the length in PCM frames here. Return MA_NOT_IMPLEMENTED and set *pLength to 0
> if there is no notion of a length or if the length is unknown.
979 |     }
980 |
981 |     static ma_data_source_vtable g_my_data_source_vtable =
982 |     {
983 |         my_data_source_read,
984 |         my_data_source_seek,
985 |         my_data_source_get_data_format,
986 |         my_data_source_get_cursor,
987 |         my_data_source_get_length
988 |     };

```

```

989 |
990 |     ma_result my_data_source_init(my_data_source* pMyDataSource)
991 |     {
992 |         ma_result result;
993 |         ma_data_source_config baseConfig;
994 |
995 |         baseConfig = ma_data_source_config_init();
996 |         baseConfig.vtable = &g_my_data_source_vtable;
997 |
998 |         result = ma_data_source_init(&baseConfig, &pMyDataSource->base);
999 |         if (result != MA_SUCCESS) {
1000 |             return result;
1001 |         }
1002 |
1003 |         // ... do the initialization of your custom data source here ...
1004 |
1005 |         return MA_SUCCESS;
1006 |     }
1007 |
1008 |     void my_data_source_uninit(my_data_source* pMyDataSource)
1009 |     {
1010 |         // ... do the uninitialization of your custom data source here ...
1011 |
1012 |         // You must uninitialize the base data source.
1013 |         ma_data_source_uninit(&pMyDataSource->base);
1014 |     }
1015 |     ...
1016 |
1017 | Note that `ma_data_source_init()` and `ma_data_source_uninit()` are never called directly outside
1018 | of the custom data source. It's up to the custom data source itself to call these within their own
1019 | init/uninit functions.
1020 |
1021 |
1022 |
1023 | 5. Engine
1024 | =====
1025 | The `ma_engine` API is a high level API for managing and mixing sounds and effect processing. The
1026 | `ma_engine` object encapsulates a resource manager and a node graph, both of which will be
1027 | explained in more detail later.
1028 |
1029 | Sounds are called `ma_sound` and are created from an engine. Sounds can be associated with a mixing
1030 | group called `ma_sound_group` which are also created from the engine. Both `ma_sound` and
1031 | `ma_sound_group` objects are nodes within the engine's node graph.
1032 |
1033 | When the engine is initialized, it will normally create a device internally. If you would rather
1034 | manage the device yourself, you can do so and just pass a pointer to it via the engine config when
1035 | you initialize the engine. You can also just use the engine without a device, which again can be
1036 | configured via the engine config.
1037 |
1038 | The most basic way to initialize the engine is with a default config, like so:
1039 |
1040 |     ```c
1041 |     ma_result result;
1042 |     ma_engine engine;
1043 |
1044 |     result = ma_engine_init(NULL, &engine);
1045 |     if (result != MA_SUCCESS) {
1046 |         return result; // Failed to initialize the engine.
1047 |     }
1048 |     ...
1049 |
1050 | This will result in the engine initializing a playback device using the operating system's default
1051 | device. This will be sufficient for many use cases, but if you need more flexibility you'll want to
1052 | configure the engine with an engine config:
1053 |
1054 |     ```c
1055 |     ma_result result;
1056 |     ma_engine engine;
1057 |     ma_engine_config engineConfig;
1058 |
1059 |     engineConfig = ma_engine_config_init();
1060 |     engineConfig.pDevice = &myDevice;
1061 |
1062 |     result = ma_engine_init(&engineConfig, &engine);
1063 |     if (result != MA_SUCCESS) {
1064 |         return result; // Failed to initialize the engine.
1065 |     }
1066 |     ...
1067 |

```

```

1068 | In the example above we're passing in a pre-initialized device. Since the caller is the one in
1069 | control of the device's data callback, it's their responsibility to manually call
1070 | `ma_engine_read_pcm_frames()` from inside their data callback:
1071 |
1072 |     ```c
1073 |     void playback_data_callback(ma_device* pDevice, void* pOutput, const void* pInput, ma_uint32
> frameCount)
1074 |     {
1075 |         ma_engine_read_pcm_frames(&g_Engine, pOutput, frameCount, NULL);
1076 |     }
1077 |     ```
1078 |
1079 | You can also use the engine independent of a device entirely:
1080 |
1081 |     ```c
1082 |     ma_result result;
1083 |     ma_engine engine;
1084 |     ma_engine_config engineConfig;
1085 |
1086 |     engineConfig = ma_engine_config_init();
1087 |     engineConfig.noDevice = MA_TRUE;
1088 |     engineConfig.channels = 2;           // Must be set when not using a device.
1089 |     engineConfig.sampleRate = 48000;    // Must be set when not using a device.
1090 |
1091 |     result = ma_engine_init(&engineConfig, &engine);
1092 |     if (result != MA_SUCCESS) {
1093 |         return result; // Failed to initialize the engine.
1094 |     }
1095 |     ```
1096 |
1097 | Note that when you're not using a device, you must set the channel count and sample rate in the
1098 | config or else miniaudio won't know what to use (miniaudio will use the device to determine this
1099 | normally). When not using a device, you need to use `ma_engine_read_pcm_frames()` to process audio
1100 | data from the engine. This kind of setup is useful if you want to do something like offline
1101 | processing or want to use a different audio system for playback such as SDL.
1102 |
1103 | When a sound is loaded it goes through a resource manager. By default the engine will initialize a
1104 | resource manager internally, but you can also specify a pre-initialized resource manager:
1105 |
1106 |     ```c
1107 |     ma_result result;
1108 |     ma_engine engine1;
1109 |     ma_engine engine2;
1110 |     ma_engine_config engineConfig;
1111 |
1112 |     engineConfig = ma_engine_config_init();
1113 |     engineConfig.pResourceManager = &myResourceManager;
1114 |
1115 |     ma_engine_init(&engineConfig, &engine1);
1116 |     ma_engine_init(&engineConfig, &engine2);
1117 |     ```
1118 |
1119 | In this example we are initializing two engines, both of which are sharing the same resource
1120 | manager. This is especially useful for saving memory when loading the same file across multiple
1121 | engines. If you were not to use a shared resource manager, each engine instance would use their own
1122 | which would result in any sounds that are used between both engine's being loaded twice. By using
1123 | a shared resource manager, it would only be loaded once. Using multiple engine's is useful when you
1124 | need to output to multiple playback devices, such as in a local multiplayer game where each player
1125 | is using their own set of headphones.
1126 |
1127 | By default an engine will be in a started state. To make it so the engine is not automatically
1128 | started you can configure it as such:
1129 |
1130 |     ```c
1131 |     engineConfig.noAutoStart = MA_TRUE;
1132 |
1133 |     // The engine will need to be started manually.
1134 |     ma_engine_start(&engine);
1135 |
1136 |     // Later on the engine can be stopped with ma_engine_stop().
1137 |     ma_engine_stop(&engine);
1138 |     ```
1139 |
1140 | The concept of starting or stopping an engine is only relevant when using the engine with a
1141 | device. Attempting to start or stop an engine that is not associated with a device will result in
1142 | `MA_INVALID_OPERATION`.
1143 |
1144 | The master volume of the engine can be controlled with `ma_engine_set_volume()` which takes a
1145 | linear scale, with 0 resulting in silence and anything above 1 resulting in amplification. If you

```

```

1146 | prefer decibel based volume control, use `ma_volume_db_to_linear()` to convert from dB to linear.
1147 |
1148 | When a sound is spatialized, it is done so relative to a listener. An engine can be configured to
1149 | have multiple listeners which can be configured via the config:
1150 |
1151 |     ```c
1152 |     engineConfig.listenerCount = 2;
1153 |     ```
1154 |
1155 | The maximum number of listeners is restricted to `MA_ENGINE_MAX_LISTENERS`. By default, when a
1156 | sound is spatialized, it will be done so relative to the closest listener. You can also pin a sound
1157 | to a specific listener which will be explained later. Listener's have a position, direction, cone,
1158 | and velocity (for doppler effect). A listener is referenced by an index, the meaning of which is up
1159 | to the caller (the index is 0 based and cannot go beyond the listener count, minus 1). The
1160 | position, direction and velocity are all specified in absolute terms:
1161 |
1162 |     ```c
1163 |     ma_engine_listener_set_position(&engine, listenerIndex, worldPosX, worldPosY, worldPosZ);
1164 |     ```
1165 |
1166 | The direction of the listener represents it's forward vector. The listener's up vector can also be
1167 | specified and defaults to +1 on the Y axis.
1168 |
1169 |     ```c
1170 |     ma_engine_listener_set_direction(&engine, listenerIndex, forwardX, forwardY, forwardZ);
1171 |     ma_engine_listener_set_world_up(&engine, listenerIndex, 0, 1, 0);
1172 |     ```
1173 |
1174 | The engine supports directional attenuation. The listener can have a cone the controls how sound is
1175 | attenuated based on the listener's direction. When a sound is between the inner and outer cones, it
1176 | will be attenuated between 1 and the cone's outer gain:
1177 |
1178 |     ```c
1179 |     ma_engine_listener_set_cone(&engine, listenerIndex, innerAngleInRadians, outerAngleInRadians,
> outerGain);
1180 |     ```
1181 |
1182 | When a sound is inside the inner cone, no directional attenuation is applied. When the sound is
1183 | outside of the outer cone, the attenuation will be set to `outerGain` in the example above. When
1184 | the sound is in between the inner and outer cones, the attenuation will be interpolated between 1
1185 | and the outer gain.
1186 |
1187 | The engine's coordinate system follows the OpenGL coordinate system where positive X points right,
1188 | positive Y points up and negative Z points forward.
1189 |
1190 | The simplest and least flexible way to play a sound is like so:
1191 |
1192 |     ```c
1193 |     ma_engine_play_sound(&engine, "my_sound.wav", pGroup);
1194 |     ```
1195 |
1196 | This is a "fire and forget" style of function. The engine will manage the `ma_sound` object
1197 | internally. When the sound finishes playing, it'll be put up for recycling. For more flexibility
1198 | you'll want to initialize a sound object:
1199 |
1200 |     ```c
1201 |     ma_sound sound;
1202 |
1203 |     result = ma_sound_init_from_file(&engine, "my_sound.wav", flags, pGroup, NULL, &sound);
1204 |     if (result != MA_SUCCESS) {
1205 |         return result; // Failed to load sound.
1206 |     }
1207 |     ```
1208 |
1209 | Sounds need to be uninitialized with `ma_sound_uninit()`.
1210 |
1211 | The example above loads a sound from a file. If the resource manager has been disabled you will not
1212 | be able to use this function and instead you'll need to initialize a sound directly from a data
1213 | source:
1214 |
1215 |     ```c
1216 |     ma_sound sound;
1217 |
1218 |     result = ma_sound_init_from_data_source(&engine, &dataSource, flags, pGroup, &sound);
1219 |     if (result != MA_SUCCESS) {
1220 |         return result;
1221 |     }
1222 |     ```
1223 |

```

```

1224 | Each `ma_sound` object represents a single instance of the sound. If you want to play the same
1225 | sound multiple times at the same time, you need to initialize a separate `ma_sound` object.
1226 |
1227 | For the most flexibility when initializing sounds, use `ma_sound_init_ex()`. This uses miniaudio's
1228 | standard config/init pattern:
1229 |
1230 |     ```c
1231 |     ma_sound sound;
1232 |     ma_sound_config soundConfig;
1233 |
1234 |     soundConfig = ma_sound_config_init();
1235 |     soundConfig.pFilePath = NULL; // Set this to load from a file path.
1236 |     soundConfig.pDataSource = NULL; // Set this to initialize from an existing data source.
1237 |     soundConfig.pInitialAttachment = &someNodeInTheNodeGraph;
1238 |     soundConfig.initialAttachmentInputBusIndex = 0;
1239 |     soundConfig.channelsIn = 1;
1240 |     soundConfig.channelsOut = 0; // Set to 0 to use the engine's native channel count.
1241 |
1242 |     result = ma_sound_init_ex(&soundConfig, &sound);
1243 |     if (result != MA_SUCCESS) {
1244 |         return result;
1245 |     }
1246 |     ```
1247 |
1248 | In the example above, the sound is being initialized without a file nor a data source. This is
1249 | valid, in which case the sound acts as a node in the middle of the node graph. This means you can
1250 | connect other sounds to this sound and allow it to act like a sound group. Indeed, this is exactly
1251 | what a `ma_sound_group` is.
1252 |
1253 | When loading a sound, you specify a set of flags that control how the sound is loaded and what
1254 | features are enabled for that sound. When no flags are set, the sound will be fully loaded into
1255 | memory in exactly the same format as how it's stored on the file system. The resource manager will
1256 | allocate a block of memory and then load the file directly into it. When reading audio data, it
1257 | will be decoded dynamically on the fly. In order to save processing time on the audio thread, it
1258 | might be beneficial to pre-decode the sound. You can do this with the `MA_SOUND_FLAG_DECODE` flag:
1259 |
1260 |     ```c
1261 |     ma_sound_init_from_file(&engine, "my_sound.wav", MA_SOUND_FLAG_DECODE, pGroup, NULL, &sound);
1262 |     ```
1263 |
1264 | By default, sounds will be loaded synchronously, meaning `ma_sound_init_*()` will not return until
1265 | the sound has been fully loaded. If this is prohibitive you can instead load sounds asynchronously
1266 | by specifying the `MA_SOUND_FLAG_ASYNC` flag:
1267 |
1268 |     ```c
1269 |     ma_sound_init_from_file(&engine, "my_sound.wav", MA_SOUND_FLAG_DECODE | MA_SOUND_FLAG_ASYNC,
> pGroup, NULL, &sound);
1270 |     ```
1271 |
1272 | This will result in `ma_sound_init_*()` returning quickly, but the sound won't yet have been fully
1273 | loaded. When you start the sound, it won't output anything until some sound is available. The sound
1274 | will start outputting audio before the sound has been fully decoded when the `MA_SOUND_FLAG_DECODE`
1275 | is specified.
1276 |
1277 | If you need to wait for an asynchronously loaded sound to be fully loaded, you can use a fence. A
1278 | fence in miniaudio is a simple synchronization mechanism which simply blocks until it's internal
1279 | counter hit's zero. You can specify a fence like so:
1280 |
1281 |     ```c
1282 |     ma_result result;
1283 |     ma_fence fence;
1284 |     ma_sound sounds[4];
1285 |
1286 |     result = ma_fence_init(&fence);
1287 |     if (result != MA_SUCCESS) {
1288 |         return result;
1289 |     }
1290 |
1291 |     // Load some sounds asynchronously.
1292 |     for (int iSound = 0; iSound < 4; iSound += 1) {
1293 |         ma_sound_init_from_file(&engine, mySoundFilesPaths[iSound], MA_SOUND_FLAG_DECODE |
> MA_SOUND_FLAG_ASYNC, pGroup, &fence, &sounds[iSound]);
1294 |     }
1295 |
1296 |     // ... do some other stuff here in the mean time ...
1297 |
1298 |     // Wait for all sounds to finish loading.
1299 |     ma_fence_wait(&fence);
1300 |     ```

```

```

1301 |
1302 | If loading the entire sound into memory is prohibitive, you can also configure the engine to stream
1303 | the audio data:
1304 |
1305 |     ```c
1306 |     ma_sound_init_from_file(&engine, "my_sound.wav", MA_SOUND_FLAG_STREAM, pGroup, NULL, &sound);
1307 |     ```
1308 |
1309 | When streaming sounds, 2 seconds worth of audio data is stored in memory. Although it should work
1310 | fine, it's inefficient to use streaming for short sounds. Streaming is useful for things like music
1311 | tracks in games.
1312 |
1313 | When loading a sound from a file path, the engine will reference count the file to prevent it from
1314 | being loaded if it's already in memory. When you uninitialize a sound, the reference count will be
1315 | decremented, and if it hits zero, the sound will be unloaded from memory. This reference counting
1316 | system is not used for streams. The engine will use a 64-bit hash of the file name when comparing
1317 | file paths which means there's a small chance you might encounter a name collision. If this is an
1318 | issue, you'll need to use a different name for one of the colliding file paths, or just not load
1319 | from files and instead load from a data source.
1320 |
1321 | You can use `ma_sound_init_copy()` to initialize a copy of another sound. Note, however, that this
1322 | only works for sounds that were initialized with `ma_sound_init_from_file()` and without the
1323 | `MA_SOUND_FLAG_STREAM` flag.
1324 |
1325 | When you initialize a sound, if you specify a sound group the sound will be attached to that group
1326 | automatically. If you set it to NULL, it will be automatically attached to the engine's endpoint.
1327 | If you would instead rather leave the sound unattached by default, you can specify the
1328 | `MA_SOUND_FLAG_NO_DEFAULT_ATTACHMENT` flag. This is useful if you want to set up a complex node
1329 | graph.
1330 |
1331 | Sounds are not started by default. To start a sound, use `ma_sound_start()`. Stop a sound with
1332 | `ma_sound_stop()`.
1333 |
1334 | Sounds can have their volume controlled with `ma_sound_set_volume()` in the same way as the
1335 | engine's master volume.
1336 |
1337 | Sounds support stereo panning and pitching. Set the pan with `ma_sound_set_pan()`. Setting the pan
1338 | to 0 will result in an unpanned sound. Setting it to -1 will shift everything to the left, whereas
1339 | +1 will shift it to the right. The pitch can be controlled with `ma_sound_set_pitch()`. A larger
1340 | value will result in a higher pitch. The pitch must be greater than 0.
1341 |
1342 | The engine supports 3D spatialization of sounds. By default sounds will have spatialization
1343 | enabled, but if a sound does not need to be spatialized it's best to disable it. There are two ways
1344 | to disable spatialization of a sound:
1345 |
1346 |     ```c
1347 |     // Disable spatialization at initialization time via a flag:
1348 |     ma_sound_init_from_file(&engine, "my_sound.wav", MA_SOUND_FLAG_NO_SPATIALIZATION, NULL, NULL,
1349 | > &sound);
1350 |
1351 |     // Dynamically disable or enable spatialization post-initialization:
1352 |     ma_sound_set_spatialization_enabled(&sound, isSpatializationEnabled);
1353 |     ```
1354 |
1355 | By default sounds will be spatialized based on the closest listener. If a sound should always be
1356 | spatialized relative to a specific listener it can be pinned to one:
1357 |
1358 |     ```c
1359 |     ma_sound_set_pinned_listener_index(&sound, listenerIndex);
1360 |     ```
1361 |
1362 | Like listeners, sounds have a position. By default, the position of a sound is in absolute space,
1363 | but it can be changed to be relative to a listener:
1364 |
1365 |     ```c
1366 |     ma_sound_set_positioning(&sound, ma_positioning_relative);
1367 |     ```
1368 |
1369 | Note that relative positioning of a sound only makes sense if there is either only one listener, or
1370 | the sound is pinned to a specific listener. To set the position of a sound:
1371 |
1372 |     ```c
1373 |     ma_sound_set_position(&sound, posX, posY, posZ);
1374 |     ```
1375 |
1376 | The direction works the same way as a listener and represents the sound's forward direction:
1377 |
1378 |     ```c
1379 |     ma_sound_set_direction(&sound, forwardX, forwardY, forwardZ);

```

```

1379 |     ``
1380 |
1381 | Sound's also have a cone for controlling directional attenuation. This works exactly the same as
1382 | listeners:
1383 |
1384 |     ``c
1385 |     ma_sound_set_cone(&sound, innerAngleInRadians, outerAngleInRadians, outerGain);
1386 |     ``
1387 |
1388 | The velocity of a sound is used for doppler effect and can be set as such:
1389 |
1390 |     ``c
1391 |     ma_sound_set_velocity(&sound, velocityX, velocityY, velocityZ);
1392 |     ``
1393 |
1394 | The engine supports different attenuation models which can be configured on a per-sound basis. By
1395 | default the attenuation model is set to `ma_attenuation_model_inverse` which is the equivalent to
1396 | OpenAL's `AL_INVERSE_DISTANCE_CLAMPED`. Configure the attenuation model like so:
1397 |
1398 |     ``c
1399 |     ma_sound_set_attenuation_model(&sound, ma_attenuation_model_inverse);
1400 |     ``
1401 |
1402 | The supported attenuation models include the following:
1403 |
1404 | +-----+-----+-----+
1405 | | ma_attenuation_model_none          | No distance attenuation.          |
1406 | +-----+-----+-----+
1407 | | ma_attenuation_model_inverse       | Equivalent to `AL_INVERSE_DISTANCE_CLAMPED`. |
1408 | +-----+-----+-----+
1409 | | ma_attenuation_model_linear        | Linear attenuation.                |
1410 | +-----+-----+-----+
1411 | | ma_attenuation_model_exponential  | Exponential attenuation.           |
1412 | +-----+-----+-----+
1413 |
1414 | To control how quickly a sound rolls off as it moves away from the listener, you need to configure
1415 | the rolloff:
1416 |
1417 |     ``c
1418 |     ma_sound_set_rolloff(&sound, rolloff);
1419 |     ``
1420 |
1421 | You can control the minimum and maximum gain to apply from spatialization:
1422 |
1423 |     ``c
1424 |     ma_sound_set_min_gain(&sound, minGain);
1425 |     ma_sound_set_max_gain(&sound, maxGain);
1426 |     ``
1427 |
1428 | Likewise, in the calculation of attenuation, you can control the minimum and maximum distances for
1429 | the attenuation calculation. This is useful if you want to ensure sounds don't drop below a certain
1430 | volume after the listener moves further away and to have sounds play a maximum volume when the
1431 | listener is within a certain distance:
1432 |
1433 |     ``c
1434 |     ma_sound_set_min_distance(&sound, minDistance);
1435 |     ma_sound_set_max_distance(&sound, maxDistance);
1436 |     ``
1437 |
1438 | The engine's spatialization system supports doppler effect. The doppler factor can be configure on
1439 | a per-sound basis like so:
1440 |
1441 |     ``c
1442 |     ma_sound_set_doppler_factor(&sound, dopplerFactor);
1443 |     ``
1444 |
1445 | You can fade sounds in and out with `ma_sound_set_fade_in_pcm_frames()` and
1446 | `ma_sound_set_fade_in_milliseconds()`. Set the volume to -1 to use the current volume as the
1447 | starting volume:
1448 |
1449 |     ``c
1450 |     // Fade in over 1 second.
1451 |     ma_sound_set_fade_in_milliseconds(&sound, 0, 1, 1000);
1452 |
1453 |     // ... sometime later ...
1454 |
1455 |     // Fade out over 1 second, starting from the current volume.
1456 |     ma_sound_set_fade_in_milliseconds(&sound, -1, 0, 1000);
1457 |     ``

```

```

1458 |
1459 | By default sounds will start immediately, but sometimes for timing and synchronization purposes it
1460 | can be useful to schedule a sound to start or stop:
1461 |
1462 |     ``c
1463 |     // Start the sound in 1 second from now.
1464 |     ma_sound_set_start_time_in_pcm_frames(&sound, ma_engine_get_time_in_pcm_frames(&engine) +
> (ma_engine_get_sample_rate(&engine) * 1));
1465 |
1466 |     // Stop the sound in 2 seconds from now.
1467 |     ma_sound_set_stop_time_in_pcm_frames(&sound, ma_engine_get_time_in_pcm_frames(&engine) +
> (ma_engine_get_sample_rate(&engine) * 2));
1468 |     ``c
1469 |
1470 | Note that scheduling a start time still requires an explicit call to `ma_sound_start()` before
1471 | anything will play.
1472 |
1473 | The time is specified in global time which is controlled by the engine. You can get the engine's
1474 | current time with `ma_engine_get_time_in_pcm_frames()`. The engine's global time is incremented
1475 | automatically as audio data is read, but it can be reset with `ma_engine_set_time_in_pcm_frames()`
1476 | in case it needs to be resynchronized for some reason.
1477 |
1478 | To determine whether or not a sound is currently playing, use `ma_sound_is_playing()`. This will
1479 | take the scheduled start and stop times into account.
1480 |
1481 | Whether or not a sound should loop can be controlled with `ma_sound_set_looping()`. Sounds will not
1482 | be looping by default. Use `ma_sound_is_looping()` to determine whether or not a sound is looping.
1483 |
1484 | Use `ma_sound_at_end()` to determine whether or not a sound is currently at the end. For a looping
1485 | sound this should never return true. Alternatively, you can configure a callback that will be fired
1486 | when the sound reaches the end. Note that the callback is fired from the audio thread which means
1487 | you cannot be uninitializing sound from the callback. To set the callback you can use
1488 | `ma_sound_set_end_callback()`. Alternatively, if you're using `ma_sound_init_ex()`, you can pass it
1489 | into the config like so:
1490 |
1491 |     ``c
1492 |     soundConfig.endCallback = my_end_callback;
1493 |     soundConfig.pEndCallbackUserData = pMyEndCallbackUserData;
1494 |     ``c
1495 |
1496 | The end callback is declared like so:
1497 |
1498 |     ``c
1499 |     void my_end_callback(void* pUserData, ma_sound* pSound)
1500 |     {
1501 |         ...
1502 |     }
1503 |     ``c
1504 |
1505 | Internally a sound wraps around a data source. Some APIs exist to control the underlying data
1506 | source, mainly for convenience:
1507 |
1508 |     ``c
1509 |     ma_sound_seek_to_pcm_frame(&sound, frameIndex);
1510 |     ma_sound_get_data_format(&sound, &format, &channels, &sampleRate, pChannelMap,
> channelMapCapacity);
1511 |     ma_sound_get_cursor_in_pcm_frames(&sound, &cursor);
1512 |     ma_sound_get_length_in_pcm_frames(&sound, &length);
1513 |     ``c
1514 |
1515 | Sound groups have the same API as sounds, only they are called `ma_sound_group`, and since they do
1516 | not have any notion of a data source, anything relating to a data source is unavailable.
1517 |
1518 | Internally, sound data is loaded via the `ma_decoder` API which means by default it only supports
1519 | file formats that have built-in support in miniaudio. You can extend this to support any kind of
1520 | file format through the use of custom decoders. To do this you'll need to use a self-managed
1521 | resource manager and configure it appropriately. See the "Resource Management" section below for
1522 | details on how to set this up.
1523 |
1524 |
1525 | 6. Resource Management
1526 | =====
1527 | Many programs will want to manage sound resources for things such as reference counting and
1528 | streaming. This is supported by miniaudio via the `ma_resource_manager` API.
1529 |
1530 | The resource manager is mainly responsible for the following:
1531 |
1532 | * Loading of sound files into memory with reference counting.
1533 | * Streaming of sound data.

```

```

1534 |
1535 | When loading a sound file, the resource manager will give you back a `ma_data_source` compatible
1536 | object called `ma_resource_manager_data_source`. This object can be passed into any
1537 | `ma_data_source` API which is how you can read and seek audio data. When loading a sound file, you
1538 | specify whether or not you want the sound to be fully loaded into memory (and optionally
1539 | pre-decoded) or streamed. When loading into memory, you can also specify whether or not you want
1540 | the data to be loaded asynchronously.
1541 |
1542 | The example below is how you can initialize a resource manager using it's default configuration:
1543 |
1544 | ```c
1545 |     ma_resource_manager_config config;
1546 |     ma_resource_manager resourceManager;
1547 |
1548 |     config = ma_resource_manager_config_init();
1549 |     result = ma_resource_manager_init(&config, &resourceManager);
1550 |     if (result != MA_SUCCESS) {
1551 |         ma_device_uninit(&device);
1552 |         printf("Failed to initialize the resource manager.");
1553 |         return -1;
1554 |     }
1555 | ```
1556 |
1557 | You can configure the format, channels and sample rate of the decoded audio data. By default it
1558 | will use the file's native data format, but you can configure it to use a consistent format. This
1559 | is useful for offloading the cost of data conversion to load time rather than dynamically
1560 | converting at mixing time. To do this, you configure the decoded format, channels and sample rate
1561 | like the code below:
1562 |
1563 | ```c
1564 |     config = ma_resource_manager_config_init();
1565 |     config.decodedFormat = device.playback.format;
1566 |     config.decodedChannels = device.playback.channels;
1567 |     config.decodedSampleRate = device.sampleRate;
1568 | ```
1569 |
1570 | In the code above, the resource manager will be configured so that any decoded audio data will be
1571 | pre-converted at load time to the device's native data format. If instead you used defaults and
1572 | the data format of the file did not match the device's data format, you would need to convert the
1573 | data at mixing time which may be prohibitive in high-performance and large scale scenarios like
1574 | games.
1575 |
1576 | Internally the resource manager uses the `ma_decoder` API to load sounds. This means by default it
1577 | only supports decoders that are built into miniaudio. It's possible to support additional encoding
1578 | formats through the use of custom decoders. To do so, pass in your `ma_decoding_backend_vtable`
1579 | vtables into the resource manager config:
1580 |
1581 | ```c
1582 |     ma_decoding_backend_vtable* pCustomBackendVTables[] =
1583 |     {
1584 |         &g_ma_decoding_backend_vtable_libvorbis,
1585 |         &g_ma_decoding_backend_vtable_libopus
1586 |     };
1587 |
1588 |     ...
1589 |
1590 |     resourceManagerConfig.ppCustomDecodingBackendVTables = pCustomBackendVTables;
1591 |     resourceManagerConfig.customDecodingBackendCount = sizeof(pCustomBackendVTables) /
1592 | > sizeof(pCustomBackendVTables[0]);
1593 |     resourceManagerConfig.pCustomDecodingBackendUserData = NULL;
1594 | ```
1595 |
1596 | This system can allow you to support any kind of file format. See the "Decoding" section for
1597 | details on how to implement custom decoders. The miniaudio repository includes examples for Opus
1598 | via libopus and libopusfile and Vorbis via libvorbis and libvorbisfile.
1599 |
1600 | Asynchronicity is achieved via a job system. When an operation needs to be performed, such as the
1601 | decoding of a page, a job will be posted to a queue which will then be processed by a job thread.
1602 | By default there will be only one job thread running, but this can be configured, like so:
1603 |
1604 | ```c
1605 |     config = ma_resource_manager_config_init();
1606 |     config.jobThreadCount = MY_JOB_THREAD_COUNT;
1607 | ```
1608 |
1609 | By default job threads are managed internally by the resource manager, however you can also self
1610 | manage your job threads if, for example, you want to integrate the job processing into your
1611 | existing job infrastructure, or if you simply don't like the way the resource manager does it. To
    do this, just set the job thread count to 0 and process jobs manually. To process jobs, you first

```

```

1612 | need to retrieve a job using `ma_resource_manager_next_job()` and then process it using
1613 | `ma_job_process()`:
1614 |
1615 |     ``c
1616 |         config = ma_resource_manager_config_init();
1617 |         config.jobThreadCount = 0;                                // Don't manage any job threads
> internally.
1618 |         config.flags = MA_RESOURCE_MANAGER_FLAG_NON_BLOCKING; // Optional. Makes
> `ma_resource_manager_next_job()` non-blocking.
1619 |
1620 |         // ... Initialize your custom job threads ...
1621 |
1622 |         void my_custom_job_thread(...)
1623 |         {
1624 |             for (;;) {
1625 |                 ma_job job;
1626 |                 ma_result result = ma_resource_manager_next_job(pMyResourceManager, &job);
1627 |                 if (result != MA_SUCCESS) {
1628 |                     if (result == MA_NO_DATA_AVAILABLE) {
1629 |                         // No jobs are available. Keep going. Will only get this if the resource manager
> was initialized
1630 |                             // with MA_RESOURCE_MANAGER_FLAG_NON_BLOCKING.
1631 |                             continue;
1632 |                         } else if (result == MA_CANCELLED) {
1633 |                             // MA_JOB_TYPE_QUIT was posted. Exit.
1634 |                             break;
1635 |                         } else {
1636 |                             // Some other error occurred.
1637 |                             break;
1638 |                         }
1639 |                     }
1640 |
1641 |                     ma_job_process(&job);
1642 |                 }
1643 |             }
1644 |         }
1645 |
1646 | In the example above, the `MA_JOB_TYPE_QUIT` event is the used as the termination
1647 | indicator, but you can use whatever you would like to terminate the thread. The call to
1648 | `ma_resource_manager_next_job()` is blocking by default, but can be configured to be non-blocking
1649 | by initializing the resource manager with the `MA_RESOURCE_MANAGER_FLAG_NON_BLOCKING` configuration
1650 | flag. Note that the `MA_JOB_TYPE_QUIT` will never be removed from the job queue. This
1651 | is to give every thread the opportunity to catch the event and terminate naturally.
1652 |
1653 | When loading a file, it's sometimes convenient to be able to customize how files are opened and
1654 | read instead of using standard `fopen()`, `fclose()`, etc. which is what miniaudio will use by
1655 | default. This can be done by setting `pVFS` member of the resource manager's config:
1656 |
1657 |     ``c
1658 |         // Initialize your custom VFS object. See documentation for VFS for information on how to do
> this.
1659 |         my_custom_vfs vfs = my_custom_vfs_init();
1660 |
1661 |         config = ma_resource_manager_config_init();
1662 |         config.pVFS = &vfs;
1663 |     ``c
1664 |
1665 | This is particularly useful in programs like games where you want to read straight from an archive
1666 | rather than the normal file system. If you do not specify a custom VFS, the resource manager will
1667 | use the operating system's normal file operations.
1668 |
1669 | To load a sound file and create a data source, call `ma_resource_manager_data_source_init()`. When
1670 | loading a sound you need to specify the file path and options for how the sounds should be loaded.
1671 | By default a sound will be loaded synchronously. The returned data source is owned by the caller
1672 | which means the caller is responsible for the allocation and freeing of the data source. Below is
1673 | an example for initializing a data source:
1674 |
1675 |     ``c
1676 |         ma_resource_manager_data_source dataSource;
1677 |         ma_result result = ma_resource_manager_data_source_init(pResourceManager, pFilePath, flags,
> &dataSource);
1678 |         if (result != MA_SUCCESS) {
1679 |             // Error.
1680 |         }
1681 |
1682 |         // ...
1683 |
1684 |         // A ma_resource_manager_data_source object is compatible with the `ma_data_source` API. To read
> data, just call

```

```

1685 | // the `ma_data_source_read_pcm_frames()` like you would with any normal data source.
1686 | result = ma_data_source_read_pcm_frames(&dataSource, pDecodedData, frameCount, &framesRead);
1687 | if (result != MA_SUCCESS) {
1688 |     // Failed to read PCM frames.
1689 | }
1690 |
1691 | // ...
1692 |
1693 | ma_resource_manager_data_source_uninit(&dataSource);
1694 | ```
1695 |
1696 | The `flags` parameter specifies how you want to perform loading of the sound file. It can be a
1697 | combination of the following flags:
1698 |
1699 | ```
1700 | MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM
1701 | MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_DECODE
1702 | MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_ASYNC
1703 | MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_WAIT_INIT
1704 | MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_LOOPING
1705 | ```
1706 |
1707 | When no flags are specified (set to 0), the sound will be fully loaded into memory, but not
1708 | decoded, meaning the raw file data will be stored in memory, and then dynamically decoded when
1709 | `ma_data_source_read_pcm_frames()` is called. To instead decode the audio data before storing it in
1710 | memory, use the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_DECODE` flag. By default, the sound file will
1711 | be loaded synchronously, meaning `ma_resource_manager_data_source_init()` will only return after
1712 | the entire file has been loaded. This is good for simplicity, but can be prohibitively slow. You
1713 | can instead load the sound asynchronously using the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_ASYNC` flag.
1714 | This will result in `ma_resource_manager_data_source_init()` returning quickly, but no data will be
1715 | returned by `ma_data_source_read_pcm_frames()` until some data is available. When no data is
1716 | available because the asynchronous decoding hasn't caught up, `MA_BUSY` will be returned by
1717 | `ma_data_source_read_pcm_frames()`.
1718 |
1719 | For large sounds, it's often prohibitive to store the entire file in memory. To mitigate this, you
1720 | can instead stream audio data which you can do by specifying the
1721 | `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM` flag. When streaming, data will be decoded in 1
1722 | second pages. When a new page needs to be decoded, a job will be posted to the job queue and then
1723 | subsequently processed in a job thread.
1724 |
1725 | The `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_LOOPING` flag can be used so that the sound will loop
1726 | when it reaches the end by default. It's recommended you use this flag when you want to have a
1727 | looping streaming sound. If you try loading a very short sound as a stream, you will get a glitch.
1728 | This is because the resource manager needs to pre-fill the initial buffer at initialization time,
1729 | and if you don't specify the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_LOOPING` flag, the resource
1730 | manager will assume the sound is not looping and will stop filling the buffer when it reaches the
1731 | end, therefore resulting in a discontinuous buffer.
1732 |
1733 | For in-memory sounds, reference counting is used to ensure the data is loaded only once. This means
1734 | multiple calls to `ma_resource_manager_data_source_init()` with the same file path will result in
1735 | the file data only being loaded once. Each call to `ma_resource_manager_data_source_init()` must be
1736 | matched up with a call to `ma_resource_manager_data_source_uninit()`. Sometimes it can be useful
1737 | for a program to register self-managed raw audio data and associate it with a file path. Use the
1738 | `ma_resource_manager_register_*(())` and `ma_resource_manager_unregister_*(())` APIs to do this.
1739 | `ma_resource_manager_register_decoded_data()` is used to associate a pointer to raw, self-managed
1740 | decoded audio data in the specified data format with the specified name. Likewise,
1741 | `ma_resource_manager_register_encoded_data()` is used to associate a pointer to raw self-managed
1742 | encoded audio data (the raw file data) with the specified name. Note that these names need not be
1743 | actual file paths. When `ma_resource_manager_data_source_init()` is called (without the
1744 | `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM` flag), the resource manager will look for these
1745 | explicitly registered data buffers and, if found, will use it as the backing data for the data
1746 | source. Note that the resource manager does *not* make a copy of this data so it is up to the
1747 | caller to ensure the pointer stays valid for its lifetime. Use
1748 | `ma_resource_manager_unregister_data()` to unregister the self-managed data. You can also use
1749 | `ma_resource_manager_register_file()` and `ma_resource_manager_unregister_file()` to register and
1750 | unregister a file. It does not make sense to use the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM`
1751 | flag with a self-managed data pointer.
1752 |
1753 |
1754 | 6.1. Asynchronous Loading and Synchronization
1755 | -----
1756 | When loading asynchronously, it can be useful to poll whether or not loading has finished. Use
1757 | `ma_resource_manager_data_source_result()` to determine this. For in-memory sounds, this will
1758 | return `MA_SUCCESS` when the file has been *entirely* decoded. If the sound is still being decoded,
1759 | `MA_BUSY` will be returned. Otherwise, some other error code will be returned if the sound failed
1760 | to load. For streaming data sources, `MA_SUCCESS` will be returned when the first page has been
1761 | decoded and the sound is ready to be played. If the first page is still being decoded, `MA_BUSY`
1762 | will be returned. Otherwise, some other error code will be returned if the sound failed to load.
1763 |

```

1764 | In addition to polling, you can also use a simple synchronization object called a "fence" to wait
 1765 | for asynchronously loaded sounds to finish. This is called `ma_fence`. The advantage to using a
 1766 | fence is that it can be used to wait for a group of sounds to finish loading rather than waiting
 1767 | for sounds on an individual basis. There are two stages to loading a sound:

- 1768 |
- 1769 | * Initialization of the internal decoder; and
- 1770 | * Completion of decoding of the file (the file is fully decoded)
- 1771 |

1772 | You can specify separate fences for each of the different stages. Waiting for the initialization
 1773 | of the internal decoder is important for when you need to know the sample format, channels and
 1774 | sample rate of the file.

1775 |

1776 | The example below shows how you could use a fence when loading a number of sounds:

```
1777 |     ``c
1778 |     // This fence will be released when all sounds are finished loading entirely.
1779 |     ma_fence fence;
1780 |     ma_fence_init(&fence);
1781 |
1782 |
1783 |     // This will be passed into the initialization routine for each sound.
1784 |     ma_resource_manager_pipeline_notifications notifications =
> ma_resource_manager_pipeline_notifications_init();
1785 |     notifications.done.pFence = &fence;
1786 |
1787 |     // Now load a bunch of sounds:
1788 |     for (iSound = 0; iSound < soundCount; iSound += 1) {
1789 |         ma_resource_manager_data_source_init(pResourceManager, pSoundFilePaths[iSound], flags,
> &notifications, &pSoundSources[iSound]);
1790 |     }
1791 |
1792 |     // ... DO SOMETHING ELSE WHILE SOUNDS ARE LOADING ...
1793 |
1794 |     // Wait for loading of sounds to finish.
1795 |     ma_fence_wait(&fence);
1796 |     ``
```

1797 |

1798 | In the example above we used a fence for waiting until the entire file has been fully decoded. If
 1799 | you only need to wait for the initialization of the internal decoder to complete, you can use the
 1800 | `init` member of the `ma_resource_manager_pipeline_notifications` object:

```
1801 |     ``c
1802 |     notifications.init.pFence = &fence;
1803 |     ``
```

1804 |

1805 |

1806 | If a fence is not appropriate for your situation, you can instead use a callback that is fired on
 1807 | an individual sound basis. This is done in a very similar way to fences:

```
1808 |     ``c
1809 |     typedef struct
1810 |     {
1811 |         ma_async_notification_callbacks cb;
1812 |         void* pMyData;
1813 |     } my_notification;
1814 |
1815 |
1816 |     void my_notification_callback(ma_async_notification* pNotification)
1817 |     {
1818 |         my_notification* pMyNotification = (my_notification*)pNotification;
1819 |
1820 |         // Do something in response to the sound finishing loading.
1821 |     }
1822 |
1823 |     ...
1824 |
1825 |     my_notification myCallback;
1826 |     myCallback.cb.onSignal = my_notification_callback;
1827 |     myCallback.pMyData = pMyData;
1828 |
1829 |     ma_resource_manager_pipeline_notifications notifications =
> ma_resource_manager_pipeline_notifications_init();
1830 |     notifications.done.pNotification = &myCallback;
1831 |
1832 |     ma_resource_manager_data_source_init(pResourceManager, "my_sound.wav", flags, &notifications,
> &mySound);
1833 |     ``
```

1834 |

1835 | In the example above we just extend the `ma_async_notification_callbacks` object and pass an
 1836 | instantiation into the `ma_resource_manager_pipeline_notifications` in the same way as we did with
 1837 | the fence, only we set `pNotification` instead of `pFence`. You can set both of these at the same
 1838 | time and they should both work as expected. If using the `pNotification` system, you need to ensure

```

1839 | your `ma_async_notification_callbacks` object stays valid.
1840 |
1841 |
1842 |
1843 | 6.2. Resource Manager Implementation Details
1844 | -----
1845 | Resources are managed in two main ways:
1846 |
1847 | * By storing the entire sound inside an in-memory buffer (referred to as a data buffer)
1848 | * By streaming audio data on the fly (referred to as a data stream)
1849 |
1850 | A resource managed data source (`ma_resource_manager_data_source`) encapsulates a data buffer or
1851 | data stream, depending on whether or not the data source was initialized with the
1852 | `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM` flag. If so, it will make use of a
1853 | `ma_resource_manager_data_stream` object. Otherwise it will use a `ma_resource_manager_data_buffer`
1854 | object. Both of these objects are data sources which means they can be used with any
1855 | `ma_data_source_*()` API.
1856 |
1857 | Another major feature of the resource manager is the ability to asynchronously decode audio files.
1858 | This relieves the audio thread of time-consuming decoding which can negatively affect scalability
1859 | due to the audio thread needing to complete it's work extremely quickly to avoid glitching.
1860 | Asynchronous decoding is achieved through a job system. There is a central multi-producer,
1861 | multi-consumer, fixed-capacity job queue. When some asynchronous work needs to be done, a job is
1862 | posted to the queue which is then read by a job thread. The number of job threads can be
1863 | configured for improved scalability, and job threads can all run in parallel without needing to
1864 | worry about the order of execution (how this is achieved is explained below).
1865 |
1866 | When a sound is being loaded asynchronously, playback can begin before the sound has been fully
1867 | decoded. This enables the application to start playback of the sound quickly, while at the same
1868 | time allowing the resource manager to keep loading in the background. Since there may be less
1869 | threads than the number of sounds being loaded at a given time, a simple scheduling system is used
1870 | to keep decoding time balanced and fair. The resource manager solves this by splitting decoding
1871 | into chunks called pages. By default, each page is 1 second long. When a page has been decoded, a
1872 | new job will be posted to start decoding the next page. By dividing up decoding into pages, an
1873 | individual sound shouldn't ever delay every other sound from having their first page decoded. Of
1874 | course, when loading many sounds at the same time, there will always be an amount of time required
1875 | to process jobs in the queue so in heavy load situations there will still be some delay. To
1876 | determine if a data source is ready to have some frames read, use
1877 | `ma_resource_manager_data_source_get_available_frames()`. This will return the number of frames
1878 | available starting from the current position.
1879 |
1880 |
1881 | 6.2.1. Job Queue
1882 | -----
1883 | The resource manager uses a job queue which is multi-producer, multi-consumer, and fixed-capacity.
1884 | This job queue is not currently lock-free, and instead uses a spinlock to achieve thread-safety.
1885 | Only a fixed number of jobs can be allocated and inserted into the queue which is done through a
1886 | lock-free data structure for allocating an index into a fixed sized array, with reference counting
1887 | for mitigation of the ABA problem. The reference count is 32-bit.
1888 |
1889 | For many types of jobs it's important that they execute in a specific order. In these cases, jobs
1890 | are executed serially. For the resource manager, serial execution of jobs is only required on a
1891 | per-object basis (per data buffer or per data stream). Each of these objects stores an execution
1892 | counter. When a job is posted it is associated with an execution counter. When the job is
1893 | processed, it checks if the execution counter of the job equals the execution counter of the
1894 | owning object and if so, processes the job. If the counters are not equal, the job will be posted
1895 | back onto the job queue for later processing. When the job finishes processing the execution order
1896 | of the main object is incremented. This system means the no matter how many job threads are
1897 | executing, decoding of an individual sound will always get processed serially. The advantage to
1898 | having multiple threads comes into play when loading multiple sounds at the same time.
1899 |
1900 | The resource manager's job queue is not 100% lock-free and will use a spinlock to achieve
1901 | thread-safety for a very small section of code. This is only relevant when the resource manager
1902 | uses more than one job thread. If only using a single job thread, which is the default, the
1903 | lock should never actually wait in practice. The amount of time spent locking should be quite
1904 | short, but it's something to be aware of for those who have pedantic lock-free requirements and
1905 | need to use more than one job thread. There are plans to remove this lock in a future version.
1906 |
1907 | In addition, posting a job will release a semaphore, which on Win32 is implemented with
1908 | `ReleaseSemaphore` and on POSIX platforms via a condition variable:
1909 |
1910 | ```c
1911 | pthread_mutex_lock(&pSemaphore->lock);
1912 | {
1913 |     pSemaphore->value += 1;
1914 |     pthread_cond_signal(&pSemaphore->cond);
1915 | }
1916 | pthread_mutex_unlock(&pSemaphore->lock);
1917 | ```

```

```

1918 |
1919 | Again, this is relevant for those with strict lock-free requirements in the audio thread. To avoid
1920 | this, you can use non-blocking mode (via the `MA_JOB_QUEUE_FLAG_NON_BLOCKING`
1921 | flag) and implement your own job processing routine (see the "Resource Manager" section above for
1922 | details on how to do this).
1923 |
1924 |
1925 |
1926 | 6.2.2. Data Buffers
1927 | -----
1928 | When the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_STREAM` flag is excluded at initialization time, the
1929 | resource manager will try to load the data into an in-memory data buffer. Before doing so, however,
1930 | it will first check if the specified file is already loaded. If so, it will increment a reference
1931 | counter and just use the already loaded data. This saves both time and memory. When the data buffer
1932 | is uninitialized, the reference counter will be decremented. If the counter hits zero, the file
1933 | will be unloaded. This is a detail to keep in mind because it could result in excessive loading and
1934 | unloading of a sound. For example, the following sequence will result in a file be loaded twice,
1935 | once after the other:
1936 |
1937 |     ```c
1938 |     ma_resource_manager_data_source_init(pResourceManager, "my_file", ..., &myDataBuffer0); //
> Refcount = 1. Initial load.
1939 |     ma_resource_manager_data_source_uninit(&myDataBuffer0);                                //
> Refcount = 0. Unloaded.
1940 |
1941 |     ma_resource_manager_data_source_init(pResourceManager, "my_file", ..., &myDataBuffer1); //
> Refcount = 1. Reloaded because previous uninit() unloaded it.
1942 |     ma_resource_manager_data_source_uninit(&myDataBuffer1);                                //
> Refcount = 0. Unloaded.
1943 |     ```
1944 |
1945 | A binary search tree (BST) is used for storing data buffers as it has good balance between
1946 | efficiency and simplicity. The key of the BST is a 64-bit hash of the file path that was passed
1947 | into `ma_resource_manager_data_source_init()`. The advantage of using a hash is that it saves
1948 | memory over storing the entire path, has faster comparisons, and results in a mostly balanced BST
1949 | due to the random nature of the hash. The disadvantages are that file names are case-sensitive and
1950 | there's a small chance of name collisions. If case-sensitivity is an issue, you should normalize
1951 | your file names to upper- or lower-case before initializing your data sources. If name collisions
1952 | become an issue, you'll need to change the name of one of the colliding names or just not use the
1953 | resource manager.
1954 |
1955 | When a sound file has not already been loaded and the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_ASYNC`
1956 | flag is excluded, the file will be decoded synchronously by the calling thread. There are two
1957 | options for controlling how the audio is stored in the data buffer - encoded or decoded. When the
1958 | `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_DECODE` option is excluded, the raw file data will be stored
1959 | in memory. Otherwise the sound will be decoded before storing it in memory. Synchronous loading is
1960 | a very simple and standard process of simply adding an item to the BST, allocating a block of
1961 | memory and then decoding (if `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_DECODE` is specified).
1962 |
1963 | When the `MA_RESOURCE_MANAGER_DATA_SOURCE_FLAG_ASYNC` flag is specified, loading of the data buffer
1964 | is done asynchronously. In this case, a job is posted to the queue to start loading and then the
1965 | function immediately returns, setting an internal result code to `MA_BUSY`. This result code is
1966 | returned when the program calls `ma_resource_manager_data_source_result()`. When decoding has fully
1967 | completed `MA_SUCCESS` will be returned. This can be used to know if loading has fully completed.
1968 |
1969 | When loading asynchronously, a single job is posted to the queue of the type
1970 | `MA_JOB_TYPE_RESOURCE_MANAGER_LOAD_DATA_BUFFER_NODE`. This involves making a copy of the file path
> and
1971 | associating it with job. When the job is processed by the job thread, it will first load the file
1972 | using the VFS associated with the resource manager. When using a custom VFS, it's important that it
1973 | be completely thread-safe because it will be used from one or more job threads at the same time.
1974 | Individual files should only ever be accessed by one thread at a time, however. After opening the
1975 | file via the VFS, the job will determine whether or not the file is being decoded. If not, it
1976 | simply allocates a block of memory and loads the raw file contents into it and returns. On the
1977 | other hand, when the file is being decoded, it will first allocate a decoder on the heap and
1978 | initialize it. Then it will check if the length of the file is known. If so it will allocate a
1979 | block of memory to store the decoded output and initialize it to silence. If the size is unknown,
1980 | it will allocate room for one page. After memory has been allocated, the first page will be
1981 | decoded. If the sound is shorter than a page, the result code will be set to `MA_SUCCESS` and the
1982 | completion event will be signalled and loading is now complete. If, however, there is more to
1983 | decode, a job with the code `MA_JOB_TYPE_RESOURCE_MANAGER_PAGE_DATA_BUFFER_NODE` is posted. This job
1984 | will decode the next page and perform the same process if it reaches the end. If there is more to
1985 | decode, the job will post another `MA_JOB_TYPE_RESOURCE_MANAGER_PAGE_DATA_BUFFER_NODE` job which
> will
1986 | keep on happening until the sound has been fully decoded. For sounds of an unknown length, each
1987 | page will be linked together as a linked list. Internally this is implemented via the
1988 | `ma_paged_audio_buffer` object.
1989 |
1990 |

```

```

2070 | container around the entire graph. The `ma_node_graph` object is required for some thread-safety
2071 | issues which will be explained later. A `ma_node_graph` object is initialized using miniaudio's
2072 | standard config/init system:
2073 |
2074 |     ```c
2075 |     ma_node_graph_config nodeGraphConfig = ma_node_graph_config_init(myChannelCount);
2076 |
2077 |     result = ma_node_graph_init(&nodeGraphConfig, NULL, &nodeGraph);    // Second parameter is a
> pointer to allocation callbacks.
2078 |     if (result != MA_SUCCESS) {
2079 |         // Failed to initialize node graph.
2080 |     }
2081 |     ```
2082 |
2083 | When you initialize the node graph, you're specifying the channel count of the endpoint. The
2084 | endpoint is a special node which has one input bus and one output bus, both of which have the
2085 | same channel count, which is specified in the config. Any nodes that connect directly to the
2086 | endpoint must be configured such that their output buses have the same channel count. When you read
2087 | audio data from the node graph, it'll have the channel count you specified in the config. To read
2088 | data from the graph:
2089 |
2090 |     ```c
2091 |     ma_uint32 framesRead;
2092 |     result = ma_node_graph_read_pcm_frames(&nodeGraph, pFramesOut, frameCount, &framesRead);
2093 |     if (result != MA_SUCCESS) {
2094 |         // Failed to read data from the node graph.
2095 |     }
2096 |     ```
2097 |
2098 | When you read audio data, miniaudio starts at the node graph's endpoint node which then pulls in
2099 | data from its input attachments, which in turn recursively pull in data from their inputs, and so
2100 | on. At the start of the graph there will be some kind of data source node which will have zero
2101 | inputs and will instead read directly from a data source. The base nodes don't literally need to
2102 | read from a `ma_data_source` object, but they will always have some kind of underlying object that
2103 | sources some kind of audio. The `ma_data_source_node` node can be used to read from a
2104 | `ma_data_source`. Data is always in floating-point format and in the number of channels you
2105 | specified when the graph was initialized. The sample rate is defined by the underlying data sources.
2106 | It's up to you to ensure they use a consistent and appropriate sample rate.
2107 |
2108 | The `ma_node` API is designed to allow custom nodes to be implemented with relative ease, but
2109 | miniaudio includes a few stock nodes for common functionality. This is how you would initialize a
2110 | node which reads directly from a data source (`ma_data_source_node`) which is an example of one
2111 | of the stock nodes that comes with miniaudio:
2112 |
2113 |     ```c
2114 |     ma_data_source_node_config config = ma_data_source_node_config_init(pMyDataSource);
2115 |
2116 |     ma_data_source_node dataSourceNode;
2117 |     result = ma_data_source_node_init(&nodeGraph, &config, NULL, &dataSourceNode);
2118 |     if (result != MA_SUCCESS) {
2119 |         // Failed to create data source node.
2120 |     }
2121 |     ```
2122 |
2123 | The data source node will use the output channel count to determine the channel count of the output
2124 | bus. There will be 1 output bus and 0 input buses (data will be drawn directly from the data
2125 | source). The data source must output to floating-point (`ma_format_f32`) or else an error will be
2126 | returned from `ma_data_source_node_init()`.
2127 |
2128 | By default the node will not be attached to the graph. To do so, use `ma_node_attach_output_bus()`:
2129 |
2130 |     ```c
2131 |     result = ma_node_attach_output_bus(&dataSourceNode, 0, ma_node_graph_get_endpoint(&nodeGraph),
> 0);
2132 |     if (result != MA_SUCCESS) {
2133 |         // Failed to attach node.
2134 |     }
2135 |     ```
2136 |
2137 | The code above connects the data source node directly to the endpoint. Since the data source node
2138 | has only a single output bus, the index will always be 0. Likewise, the endpoint only has a single
2139 | input bus which means the input bus index will also always be 0.
2140 |
2141 | To detach a specific output bus, use `ma_node_detach_output_bus()`. To detach all output buses, use
2142 | `ma_node_detach_all_output_buses()`. If you want to just move the output bus from one attachment to
2143 | another, you do not need to detach first. You can just call `ma_node_attach_output_bus()` and it'll
2144 | deal with it for you.
2145 |
2146 | Less frequently you may want to create a specialized node. This will be a node where you implement

```

```

2147 | your own processing callback to apply a custom effect of some kind. This is similar to initializing
2148 | one of the stock node types, only this time you need to specify a pointer to a vtable containing a
2149 | pointer to the processing function and the number of input and output buses. Example:
2150 |
2151 |     ``c
2152 |     static void my_custom_node_process_pcm_frames(ma_node* pNode, const float** ppFramesIn,
> ma_uint32* pFrameCountIn, float** ppFramesOut, ma_uint32* pFrameCountOut)
2153 |     {
2154 |         // Do some processing of ppFramesIn (one stream of audio data per input bus)
2155 |         const float* pFramesIn_0 = ppFramesIn[0]; // Input bus @ index 0.
2156 |         const float* pFramesIn_1 = ppFramesIn[1]; // Input bus @ index 1.
2157 |         float* pFramesOut_0 = ppFramesOut[0];      // Output bus @ index 0.
2158 |
2159 |         // Do some processing. On input, `pFrameCountIn` will be the number of input frames in each
2160 |         // buffer in `ppFramesIn` and `pFrameCountOut` will be the capacity of each of the buffers
2161 |         // in `ppFramesOut`. On output, `pFrameCountIn` should be set to the number of input frames
2162 |         // your node consumed and `pFrameCountOut` should be set the number of output frames that
2163 |         // were produced.
2164 |         //
2165 |         // You should process as many frames as you can. If your effect consumes input frames at the
2166 |         // same rate as output frames (always the case, unless you're doing resampling), you need
2167 |         // only look at `ppFramesOut` and process that exact number of frames. If you're doing
2168 |         // resampling, you'll need to be sure to set both `pFrameCountIn` and `pFrameCountOut`
2169 |         // properly.
2170 |     }
2171 |
2172 |     static ma_node_vtable my_custom_node_vtable =
2173 |     {
2174 |         my_custom_node_process_pcm_frames, // The function that will be called to process your
> custom node. This is where you'd implement your effect processing.
2175 |         NULL, // Optional. A callback for calculating the number of input frames that are required
> to process a specified number of output frames.
2176 |         2,    // 2 input buses.
2177 |         1,    // 1 output bus.
2178 |         0     // Default flags.
2179 |     };
2180 |
2181 |     ...
2182 |
2183 |     // Each bus needs to have a channel count specified. To do this you need to specify the channel
2184 |     // counts in an array and then pass that into the node config.
2185 |     ma_uint32 inputChannels[2]; // Equal in size to the number of input channels specified in
> the vtable.
2186 |     ma_uint32 outputChannels[1]; // Equal in size to the number of output channels specified in
> the vtable.
2187 |
2188 |     inputChannels[0] = channelsIn;
2189 |     inputChannels[1] = channelsIn;
2190 |     outputChannels[0] = channelsOut;
2191 |
2192 |     ma_node_config nodeConfig = ma_node_config_init();
2193 |     nodeConfig.vtable = &my_custom_node_vtable;
2194 |     nodeConfig.pInputChannels = inputChannels;
2195 |     nodeConfig.pOutputChannels = outputChannels;
2196 |
2197 |     ma_node_base node;
2198 |     result = ma_node_init(&nodeGraph, &nodeConfig, NULL, &node);
2199 |     if (result != MA_SUCCESS) {
2200 |         // Failed to initialize node.
2201 |     }
2202 |     ...
2203 |
2204 | When initializing a custom node, as in the code above, you'll normally just place your vtable in
2205 | static space. The number of input and output buses are specified as part of the vtable. If you need
2206 | a variable number of buses on a per-node bases, the vtable should have the relevant bus count set
2207 | to `MA_NODE_BUS_COUNT_UNKNOWN`. In this case, the bus count should be set in the node config:
2208 |
2209 |     ``c
2210 |     static ma_node_vtable my_custom_node_vtable =
2211 |     {
2212 |         my_custom_node_process_pcm_frames, // The function that will be called process your custom
> node. This is where you'd implement your effect processing.
2213 |         NULL, // Optional. A callback for calculating the number of input frames that are required
> to process a specified number of output frames.
2214 |         MA_NODE_BUS_COUNT_UNKNOWN, // The number of input buses is determined on a per-node basis.
2215 |         1,    // 1 output bus.
2216 |         0     // Default flags.
2217 |     };
2218 |

```

```

2219 | ...
2220 |
2221 |     ma_node_config nodeConfig = ma_node_config_init();
2222 |     nodeConfig.vtable         = &my_custom_node_vtable;
2223 |     nodeConfig.inputBusCount   = myBusCount;           // <-- Since the vtable specifies
> MA_NODE_BUS_COUNT_UNKNOWN, the input bus count should be set here.
2224 |     nodeConfig.pInputChannels = inputChannels;        // <-- Make sure there are
> nodeConfig.inputBusCount elements in this array.
2225 |     nodeConfig.pOutputChannels = outputChannels;      // <-- The vtable specifies 1 output bus, so
> there must be 1 element in this array.
2226 |     ``
2227 |
2228 | In the above example it's important to never set the `inputBusCount` and `outputBusCount` members
2229 | to anything other than their defaults if the vtable specifies an explicit count. They can only be
2230 | set if the vtable specifies MA_NODE_BUS_COUNT_UNKNOWN in the relevant bus count.
2231 |
2232 | Most often you'll want to create a structure to encapsulate your node with some extra data. You
2233 | need to make sure the `ma_node_base` object is your first member of the structure:
2234 |
2235 |     ``c
2236 |     typedef struct
2237 |     {
2238 |         ma_node_base base; // <-- Make sure this is always the first member.
2239 |         float someCustomData;
2240 |     } my_custom_node;
2241 |     ``
2242 |
2243 | By doing this, your object will be compatible with all `ma_node` APIs and you can attach it to the
2244 | graph just like any other node.
2245 |
2246 | In the custom processing callback (`my_custom_node_process_pcm_frames()` in the example above), the
2247 | number of channels for each bus is what was specified by the config when the node was initialized
2248 | with `ma_node_init()`. In addition, all attachments to each of the input buses will have been
2249 | pre-mixed by miniaudio. The config allows you to specify different channel counts for each
2250 | individual input and output bus. It's up to the effect to handle it appropriately, and if it can't,
2251 | return an error in it's initialization routine.
2252 |
2253 | Custom nodes can be assigned some flags to describe their behaviour. These are set via the vtable
2254 | and include the following:
2255 |
2256 | +-----+-----+
2257 | | Flag Name | Description |
2258 | +-----+-----+
2259 | | MA_NODE_FLAG_PASSTHROUGH | Useful for nodes that do not do any kind of audio |
2260 | | | processing, but are instead used for tracking |
2261 | | | time, handling events, etc. Also used by the |
2262 | | | internal endpoint node. It reads directly from |
2263 | | | the input bus to the output bus. Nodes with this |
2264 | | | flag must have exactly 1 input bus and 1 output |
2265 | | | bus, and both buses must have the same channel |
2266 | | | counts. |
2267 | +-----+-----+
2268 | | MA_NODE_FLAG_CONTINUOUS_PROCESSING | Causes the processing callback to be called even |
2269 | | | when no data is available to be read from input |
2270 | | | attachments. When a node has at least one input |
2271 | | | bus, but there are no inputs attached or the |
2272 | | | inputs do not deliver any data, the node's |
2273 | | | processing callback will not get fired. This flag |
2274 | | | will make it so the callback is always fired |
2275 | | | regardless of whether or not any input data is |
2276 | | | received. This is useful for effects like |
2277 | | | echos where there will be a tail of audio data |
2278 | | | that still needs to be processed even when the |
2279 | | | original data sources have reached their ends. It |
2280 | | | may also be useful for nodes that must always |
2281 | | | have their processing callback fired when there |
2282 | | | are no inputs attached. |
2283 | +-----+-----+
2284 | | MA_NODE_FLAG_ALLOW_NULL_INPUT | Used in conjunction with |
2285 | | | `MA_NODE_FLAG_CONTINUOUS_PROCESSING`. When this |
2286 | | | is set, the `ppFramesIn` parameter of the |
2287 | | | processing callback will be set to NULL when |
2288 | | | there are no input frames are available. When |
2289 | | | this is unset, silence will be posted to the |
2290 | | | processing callback. |
2291 | +-----+-----+
2292 | | MA_NODE_FLAG_DIFFERENT_PROCESSING_RATES | Used to tell miniaudio that input and output |
2293 | | | frames are processed at different rates. You |
2294 | | | should set this for any nodes that perform

```

```

2295 | | resampling. |
2296 | +-----+-----+
2297 | | MA_NODE_FLAG_SILENT_OUTPUT | Used to tell miniaudio that a node produces only |
2298 | | | silent output. This is useful for nodes where you |
2299 | | | don't want the output to contribute to the final |
2300 | | | mix. An example might be if you want split your |
2301 | | | stream and have one branch be output to a file. |
2302 | | | When using this flag, you should avoid writing to |
2303 | | | the output buffer of the node's processing |
2304 | | | callback because miniaudio will ignore it anyway. |
2305 | +-----+-----+
2306 |
2307 |
2308 | If you need to make a copy of an audio stream for effect processing you can use a splitter node
2309 | called `ma_splitter_node`. This takes has 1 input bus and splits the stream into 2 output buses.
2310 | You can use it like this:
2311 |
2312 | ```c
2313 |     ma_splitter_node_config splitterNodeConfig = ma_splitter_node_config_init(channels);
2314 |
2315 |     ma_splitter_node splitterNode;
2316 |     result = ma_splitter_node_init(&nodeGraph, &splitterNodeConfig, NULL, &splitterNode);
2317 |     if (result != MA_SUCCESS) {
2318 |         // Failed to create node.
2319 |     }
2320 |
2321 |     // Attach your output buses to two different input buses (can be on two different nodes).
2322 |     ma_node_attach_output_bus(&splitterNode, 0, ma_node_graph_get_endpoint(&nodeGraph), 0); //
> Attach directly to the endpoint.
2323 |     ma_node_attach_output_bus(&splitterNode, 1, &myEffectNode, 0); //
> Attach to input bus 0 of some effect node.
2324 |     ```
2325 |
2326 | The volume of an output bus can be configured on a per-bus basis:
2327 |
2328 | ```c
2329 |     ma_node_set_output_bus_volume(&splitterNode, 0, 0.5f);
2330 |     ma_node_set_output_bus_volume(&splitterNode, 1, 0.5f);
2331 |     ```
2332 |
2333 | In the code above we're using the splitter node from before and changing the volume of each of the
2334 | copied streams.
2335 |
2336 | You can start and stop a node with the following:
2337 |
2338 | ```c
2339 |     ma_node_set_state(&splitterNode, ma_node_state_started); // The default state.
2340 |     ma_node_set_state(&splitterNode, ma_node_state_stopped);
2341 |     ```
2342 |
2343 | By default the node is in a started state, but since it won't be connected to anything won't
2344 | actually be invoked by the node graph until it's connected. When you stop a node, data will not be
2345 | read from any of its input connections. You can use this property to stop a group of sounds
2346 | atomically.
2347 |
2348 | You can configure the initial state of a node in it's config:
2349 |
2350 | ```c
2351 |     nodeConfig.initialState = ma_node_state_stopped;
2352 |     ```
2353 |
2354 | Note that for the stock specialized nodes, all of their configs will have a `nodeConfig` member
2355 | which is the config to use with the base node. This is where the initial state can be configured
2356 | for specialized nodes:
2357 |
2358 | ```c
2359 |     dataSourceNodeConfig.nodeConfig.initialState = ma_node_state_stopped;
2360 |     ```
2361 |
2362 | When using a specialized node like `ma_data_source_node` or `ma_splitter_node`, be sure to not
2363 | modify the `vtable` member of the `nodeConfig` object.
2364 |
2365 |
2366 | 7.1. Timing
2367 | -----
2368 | The node graph supports starting and stopping nodes at scheduled times. This is especially useful
2369 | for data source nodes where you want to get the node set up, but only start playback at a specific
2370 | time. There are two clocks: local and global.
2371 |

```

```

2372 | A local clock is per-node, whereas the global clock is per graph. Scheduling starts and stops can
2373 | only be done based on the global clock because the local clock will not be running while the node
2374 | is stopped. The global clocks advances whenever `ma_node_graph_read_pcm_frames()` is called. On the
2375 | other hand, the local clock only advances when the node's processing callback is fired, and is
2376 | advanced based on the output frame count.
2377 |
2378 | To retrieve the global time, use `ma_node_graph_get_time()`. The global time can be set with
2379 | `ma_node_graph_set_time()` which might be useful if you want to do seeking on a global timeline.
2380 | Getting and setting the local time is similar. Use `ma_node_get_time()` to retrieve the local time,
2381 | and `ma_node_set_time()` to set the local time. The global and local times will be advanced by the
2382 | audio thread, so care should be taken to avoid data races. Ideally you should avoid calling these
2383 | outside of the node processing callbacks which are always run on the audio thread.
2384 |
2385 | There is basic support for scheduling the starting and stopping of nodes. You can only schedule one
2386 | start and one stop at a time. This is mainly intended for putting nodes into a started or stopped
2387 | state in a frame-exact manner. Without this mechanism, starting and stopping of a node is limited
2388 | to the resolution of a call to `ma_node_graph_read_pcm_frames()` which would typically be in blocks
2389 | of several milliseconds. The following APIs can be used for scheduling node states:
2390 |
2391 |     ```c
2392 |     ma_node_set_state_time()
2393 |     ma_node_get_state_time()
2394 |     ```
2395 |
2396 | The time is absolute and must be based on the global clock. An example is below:
2397 |
2398 |     ```c
2399 |     ma_node_set_state_time(&myNode, ma_node_state_started, sampleRate*1);    // Delay starting to 1
> second.
2400 |     ma_node_set_state_time(&myNode, ma_node_state_stopped, sampleRate*5);    // Delay stopping to 5
> seconds.
2401 |     ```
2402 |
2403 | An example for changing the state using a relative time.
2404 |
2405 |     ```c
2406 |     ma_node_set_state_time(&myNode, ma_node_state_started, sampleRate*1 +
> ma_node_graph_get_time(&myNodeGraph));
2407 |     ma_node_set_state_time(&myNode, ma_node_state_stopped, sampleRate*5 +
> ma_node_graph_get_time(&myNodeGraph));
2408 |     ```
2409 |
2410 | Note that due to the nature of multi-threading the times may not be 100% exact. If this is an
2411 | issue, consider scheduling state changes from within a processing callback. An idea might be to
2412 | have some kind of passthrough trigger node that is used specifically for tracking time and handling
2413 | events.
2414 |
2415 |
2416 |
2417 | 7.2. Thread Safety and Locking
2418 | -----
2419 | When processing audio, it's ideal not to have any kind of locking in the audio thread. Since it's
2420 | expected that `ma_node_graph_read_pcm_frames()` would be run on the audio thread, it does so
2421 | without the use of any locks. This section discusses the implementation used by miniaudio and goes
2422 | over some of the compromises employed by miniaudio to achieve this goal. Note that the current
2423 | implementation may not be ideal - feedback and critiques are most welcome.
2424 |
2425 | The node graph API is not *entirely* lock-free. Only `ma_node_graph_read_pcm_frames()` is expected
2426 | to be lock-free. Attachment, detachment and uninitialization of nodes use locks to simplify the
2427 | implementation, but are crafted in a way such that such locking is not required when reading audio
2428 | data from the graph. Locking in these areas are achieved by means of spinlocks.
2429 |
2430 | The main complication with keeping `ma_node_graph_read_pcm_frames()` lock-free stems from the fact
2431 | that a node can be uninitialized, and it's memory potentially freed, while in the middle of being
2432 | processed on the audio thread. There are times when the audio thread will be referencing a node,
2433 | which means the uninitialization process of a node needs to make sure it delays returning until the
2434 | audio thread is finished so that control is not handed back to the caller thereby giving them a
2435 | chance to free the node's memory.
2436 |
2437 | When the audio thread is processing a node, it does so by reading from each of the output buses of
2438 | the node. In order for a node to process data for one of its output buses, it needs to read from
2439 | each of its input buses, and so on and so forth. It follows that once all output buses of a node
2440 | are detached, the node as a whole will be disconnected and no further processing will occur unless
2441 | it's output buses are reattached, which won't be happening when the node is being uninitialized.
2442 | By having `ma_node_detach_output_bus()` wait until the audio thread is finished with it, we can
2443 | simplify a few things, at the expense of making `ma_node_detach_output_bus()` a bit slower. By
2444 | doing this, the implementation of `ma_node_uninit()` becomes trivial - just detach all output
2445 | nodes, followed by each of the attachments to each of its input nodes, and then do any final clean
2446 | up.

```

```

2447 |
2448 | With the above design, the worst-case scenario is `ma_node_detach_output_bus()` taking as long as
2449 | it takes to process the output bus being detached. This will happen if it's called at just the
2450 | wrong moment where the audio thread has just iterated it and has just started processing. The
2451 | caller of `ma_node_detach_output_bus()` will stall until the audio thread is finished, which
2452 | includes the cost of recursively processing its inputs. This is the biggest compromise made with
2453 | the approach taken by miniaudio for its lock-free processing system. The cost of detaching nodes
2454 | earlier in the pipeline (data sources, for example) will be cheaper than the cost of detaching
2455 | higher level nodes, such as some kind of final post-processing endpoint. If you need to do mass
2456 | detachments, detach starting from the lowest level nodes and work your way towards the final
2457 | endpoint node (but don't try detaching the node graph's endpoint). If the audio thread is not
2458 | running, detachment will be fast and detachment in any order will be the same. The reason nodes
2459 | need to wait for their input attachments to complete is due to the potential for desyncs between
2460 | data sources. If the node was to terminate processing mid way through processing its inputs,
2461 | there's a chance that some of the underlying data sources will have been read, but then others not.
2462 | That will then result in a potential desynchronization when detaching and reattaching higher-level
2463 | nodes. A possible solution to this is to have an option when detaching to terminate processing
2464 | before processing all input attachments which should be fairly simple.
2465 |
2466 | Another compromise, albeit less significant, is locking when attaching and detaching nodes. This
2467 | locking is achieved by means of a spinlock in order to reduce memory overhead. A lock is present
2468 | for each input bus and output bus. When an output bus is connected to an input bus, both the output
2469 | bus and input bus is locked. This locking is specifically for attaching and detaching across
2470 | different threads and does not affect `ma_node_graph_read_pcm_frames()` in any way. The locking and
2471 | unlocking is mostly self-explanatory, but a slightly less intuitive aspect comes into it when
2472 | considering that iterating over attachments must not break as a result of attaching or detaching a
2473 | node while iteration is occurring.
2474 |
2475 | Attaching and detaching are both quite simple. When an output bus of a node is attached to an input
2476 | bus of another node, it's added to a linked list. Basically, an input bus is a linked list, where
2477 | each item in the list is an output bus. We have some intentional (and convenient) restrictions on
2478 | what can be done with the linked list in order to simplify the implementation. First of all, whenever
2479 | something needs to iterate over the list, it must do so in a forward direction. Backwards iteration
2480 | is not supported. Also, items can only be added to the start of the list.
2481 |
2482 | The linked list is a doubly-linked list where each item in the list (an output bus) holds a pointer
2483 | to the next item in the list, and another to the previous item. A pointer to the previous item is
2484 | only required for fast detachment of the node - it is never used in iteration. This is an
2485 | important property because it means from the perspective of iteration, attaching and detaching of
2486 | an item can be done with a single atomic assignment. This is exploited by both the attachment and
2487 | detachment process. When attaching the node, the first thing that is done is the setting of the
2488 | local "next" and "previous" pointers of the node. After that, the item is "attached" to the list
2489 | by simply performing an atomic exchange with the head pointer. After that, the node is "attached"
2490 | to the list from the perspective of iteration. Even though the "previous" pointer of the next item
2491 | hasn't yet been set, from the perspective of iteration it's been attached because iteration will
2492 | only be happening in a forward direction which means the "previous" pointer won't actually ever get
2493 | used. The same general process applies to detachment. See `ma_node_attach_output_bus()` and
2494 | `ma_node_detach_output_bus()` for the implementation of this mechanism.
2495 |
2496 |
2497 |
2498 | 8. Decoding
2499 | =====
2500 | The `ma_decoder` API is used for reading audio files. Decoders are completely decoupled from
2501 | devices and can be used independently. Built-in support is included for the following formats:
2502 |
2503 | +-----+
2504 | | Format |
2505 | +-----+
2506 | | WAV   |
2507 | | MP3   |
2508 | | FLAC  |
2509 | +-----+
2510 |
2511 | You can disable the built-in decoders by specifying one or more of the following options before the
2512 | miniaudio implementation:
2513 |
2514 | ```c
2515 | #define MA_NO_WAV
2516 | #define MA_NO_MP3
2517 | #define MA_NO_FLAC
2518 | ```
2519 |
2520 | miniaudio supports the ability to plug in custom decoders. See the section below for details on how
2521 | to use custom decoders.
2522 |
2523 | A decoder can be initialized from a file with `ma_decoder_init_file()`, a block of memory with
2524 | `ma_decoder_init_memory()`, or from data delivered via callbacks with `ma_decoder_init()`. Here is
2525 | an example for loading a decoder from a file:

```

```

2526 |
2527 |     ``c
2528 |     ma_decoder decoder;
2529 |     ma_result result = ma_decoder_init_file("MySong.mp3", NULL, &decoder);
2530 |     if (result != MA_SUCCESS) {
2531 |         return false;    // An error occurred.
2532 |     }
2533 |
2534 |     ...
2535 |
2536 |     ma_decoder_uninit(&decoder);
2537 |     ``c
2538 |
2539 | When initializing a decoder, you can optionally pass in a pointer to a `ma_decoder_config` object
2540 | (the `NULL` argument in the example above) which allows you to configure the output format, channel
2541 | count, sample rate and channel map:
2542 |
2543 |     ``c
2544 |     ma_decoder_config config = ma_decoder_config_init(ma_format_f32, 2, 48000);
2545 |     ``c
2546 |
2547 | When passing in `NULL` for decoder config in `ma_decoder_init*()`, the output format will be the
2548 | same as that defined by the decoding backend.
2549 |
2550 | Data is read from the decoder as PCM frames. This will output the number of PCM frames actually
2551 | read. If this is less than the requested number of PCM frames it means you've reached the end. The
2552 | return value will be `MA_AT_END` if no samples have been read and the end has been reached.
2553 |
2554 |     ``c
2555 |     ma_result result = ma_decoder_read_pcm_frames(pDecoder, pFrames, framesToRead, &framesRead);
2556 |     if (framesRead < framesToRead) {
2557 |         // Reached the end.
2558 |     }
2559 |     ``c
2560 |
2561 | You can also seek to a specific frame like so:
2562 |
2563 |     ``c
2564 |     ma_result result = ma_decoder_seek_to_pcm_frame(pDecoder, targetFrame);
2565 |     if (result != MA_SUCCESS) {
2566 |         return false;    // An error occurred.
2567 |     }
2568 |     ``c
2569 |
2570 | If you want to loop back to the start, you can simply seek back to the first PCM frame:
2571 |
2572 |     ``c
2573 |     ma_decoder_seek_to_pcm_frame(pDecoder, 0);
2574 |     ``c
2575 |
2576 | When loading a decoder, miniaudio uses a trial and error technique to find the appropriate decoding
2577 | backend. This can be unnecessarily inefficient if the type is already known. In this case you can
2578 | use `encodingFormat` variable in the device config to specify a specific encoding format you want
2579 | to decode:
2580 |
2581 |     ``c
2582 |     decoderConfig.encodingFormat = ma_encoding_format_wav;
2583 |     ``c
2584 |
2585 | See the `ma_encoding_format` enum for possible encoding formats.
2586 |
2587 | The `ma_decoder_init_file()` API will try using the file extension to determine which decoding
2588 | backend to prefer.
2589 |
2590 |
2591 | 8.1. Custom Decoders
2592 | -----
2593 | It's possible to implement a custom decoder and plug it into miniaudio. This is extremely useful
2594 | when you want to use the `ma_decoder` API, but need to support an encoding format that's not one of
2595 | the stock formats supported by miniaudio. This can be put to particularly good use when using the
2596 | `ma_engine` and/or `ma_resource_manager` APIs because they use `ma_decoder` internally. If, for
2597 | example, you wanted to support Opus, you can do so with a custom decoder (there is a reference
2598 | Opus decoder in the "extras" folder of the miniaudio repository which uses libopus + libopusfile).
2599 |
2600 | A custom decoder must implement a data source. A vtable called `ma_decoding_backend_vtable` needs
2601 | to be implemented which is then passed into the decoder config:
2602 |
2603 |     ``c
2604 |     ma_decoding_backend_vtable* pCustomBackendVTables[] =

```

```

2605 | {
2606 |     &g_ma_decoding_backend_vtable_libvorbis,
2607 |     &g_ma_decoding_backend_vtable_libopus
2608 | };
2609 |
2610 | ...
2611 |
2612 | decoderConfig = ma_decoder_config_init_default();
2613 | decoderConfig.pCustomBackendUserData = NULL;
2614 | decoderConfig.ppCustomBackendVTables = pCustomBackendVTables;
2615 | decoderConfig.customBackendCount = sizeof(pCustomBackendVTables) /
> sizeof(pCustomBackendVTables[0]);
2616 | ```
2617 |
2618 | The `ma_decoding_backend_vtable` vtable has the following functions:
2619 |
2620 | ```
2621 |     onInit
2622 |     onInitFile
2623 |     onInitFileW
2624 |     onInitMemory
2625 |     onUninit
2626 | ```
2627 |
2628 | There are only two functions that must be implemented - `onInit` and `onUninit`. The other
2629 | functions can be implemented for a small optimization for loading from a file path or memory. If
2630 | these are not specified, miniaudio will deal with it for you via a generic implementation.
2631 |
2632 | When you initialize a custom data source (by implementing the `onInit` function in the vtable) you
2633 | will need to output a pointer to a `ma_data_source` which implements your custom decoder. See the
2634 | section about data sources for details on how to implement this. Alternatively, see the
2635 | "custom_decoders" example in the miniaudio repository.
2636 |
2637 | The `onInit` function takes a pointer to some callbacks for the purpose of reading raw audio data
2638 | from some arbitrary source. You'll use these functions to read from the raw data and perform the
2639 | decoding. When you call them, you will pass in the `pReadSeekTellUserData` pointer to the relevant
2640 | parameter.
2641 |
2642 | The `pConfig` parameter in `onInit` can be used to configure the backend if appropriate. It's only
2643 | used as a hint and can be ignored. However, if any of the properties are relevant to your decoder,
2644 | an optimal implementation will handle the relevant properties appropriately.
2645 |
2646 | If memory allocation is required, it should be done so via the specified allocation callbacks if
2647 | possible (the `pAllocationCallbacks` parameter).
2648 |
2649 | If an error occurs when initializing the decoder, you should leave `ppBackend` unset, or set to
2650 | NULL, and make sure everything is cleaned up appropriately and an appropriate result code returned.
2651 | When multiple custom backends are specified, miniaudio will cycle through the vtables in the order
2652 | they're listed in the array that's passed into the decoder config so it's important that your
2653 | initialization routine is clean.
2654 |
2655 | When a decoder is uninitialized, the `onUninit` callback will be fired which will give you an
2656 | opportunity to clean up and internal data.
2657 |
2658 |
2659 |
2660 | 9. Encoding
2661 | =====
2662 | The `ma_encoding` API is used for writing audio files. The only supported output format is WAV.
2663 | This can be disabled by specifying the following option before the implementation of miniaudio:
2664 |
2665 | ```c
2666 | #define MA_NO_WAV
2667 | ```
2668 |
2669 | An encoder can be initialized to write to a file with `ma_encoder_init_file()` or from data
2670 | delivered via callbacks with `ma_encoder_init()`. Below is an example for initializing an encoder
2671 | to output to a file.
2672 |
2673 | ```c
2674 | ma_encoder_config config = ma_encoder_config_init(ma_encoding_format_wav, FORMAT, CHANNELS,
> SAMPLE_RATE);
2675 | ma_encoder encoder;
2676 | ma_result result = ma_encoder_init_file("my_file.wav", &config, &encoder);
2677 | if (result != MA_SUCCESS) {
2678 |     // Error
2679 | }
2680 |
2681 | ...

```

```

2682 |
2683 |     ma_encoder_uninit(&encoder);
2684 |     ```
2685 |
2686 | When initializing an encoder you must specify a config which is initialized with
2687 | `ma_encoder_config_init()`. Here you must specify the file type, the output sample format, output
2688 | channel count and output sample rate. The following file types are supported:
2689 |
2690 | +-----+-----+
2691 | | Enum           | Description |
2692 | +-----+-----+
2693 | | ma_encoding_format_wav | WAV         |
2694 | +-----+-----+
2695 |
2696 | If the format, channel count or sample rate is not supported by the output file type an error will
2697 | be returned. The encoder will not perform data conversion so you will need to convert it before
2698 | outputting any audio data. To output audio data, use `ma_encoder_write_pcm_frames()`, like in the
2699 | example below:
2700 |
2701 |     ```c
2702 |     ma_uint64 framesWritten;
2703 |     result = ma_encoder_write_pcm_frames(&encoder, pCMFramesToWrite, framesToWrite,
> &framesWritten);
2704 |     if (result != MA_SUCCESS) {
2705 |         ... handle error ...
2706 |     }
2707 |     ```
2708 |
2709 | The `framesWritten` variable will contain the number of PCM frames that were actually written. This
2710 | is optionally and you can pass in `NULL` if you need this.
2711 |
2712 | Encoders must be uninitialized with `ma_encoder_uninit()`.
2713 |
2714 |
2715 |
2716 | 10. Data Conversion
2717 | =====
2718 | A data conversion API is included with miniaudio which supports the majority of data conversion
2719 | requirements. This supports conversion between sample formats, channel counts (with channel
2720 | mapping) and sample rates.
2721 |
2722 |
2723 | 10.1. Sample Format Conversion
2724 | -----
2725 | Conversion between sample formats is achieved with the `ma_pcm*_to_*()`, `ma_pcm_convert()` and
2726 | `ma_convert_pcm_frames_format()` APIs. Use `ma_pcm*_to_*()` to convert between two specific
2727 | formats. Use `ma_pcm_convert()` to convert based on a `ma_format` variable. Use
2728 | `ma_convert_pcm_frames_format()` to convert PCM frames where you want to specify the frame count
2729 | and channel count as a variable instead of the total sample count.
2730 |
2731 |
2732 | 10.1.1. Dithering
2733 | -----
2734 | Dithering can be set using the ditherMode parameter.
2735 |
2736 | The different dithering modes include the following, in order of efficiency:
2737 |
2738 | +-----+-----+
2739 | | Type          | Enum Token   |
2740 | +-----+-----+
2741 | | None          | ma_dither_mode_none |
2742 | | Rectangle     | ma_dither_mode_rectangle |
2743 | | Triangle      | ma_dither_mode_triangle |
2744 | +-----+-----+
2745 |
2746 | Note that even if the dither mode is set to something other than `ma_dither_mode_none`, it will be
2747 | ignored for conversions where dithering is not needed. Dithering is available for the following
2748 | conversions:
2749 |
2750 |     ```
2751 |     s16 -> u8
2752 |     s24 -> u8
2753 |     s32 -> u8
2754 |     f32 -> u8
2755 |     s24 -> s16
2756 |     s32 -> s16
2757 |     f32 -> s16
2758 |     ```
2759 |

```

```

2760 | Note that it is not an error to pass something other than ma_dither_mode_none for conversions where
2761 | dither is not used. It will just be ignored.
2762 |
2763 |
2764 |
2765 | 10.2. Channel Conversion
2766 | -----
2767 | Channel conversion is used for channel rearrangement and conversion from one channel count to
2768 | another. The `ma_channel_converter` API is used for channel conversion. Below is an example of
2769 | initializing a simple channel converter which converts from mono to stereo.
2770 |
2771 |     ```c
2772 |     ma_channel_converter_config config = ma_channel_converter_config_init(
2773 |         ma_format,           // Sample format
2774 |         1,                   // Input channels
2775 |         NULL,                 // Input channel map
2776 |         2,                   // Output channels
2777 |         NULL,                 // Output channel map
2778 |         ma_channel_mix_mode_default); // The mixing algorithm to use when combining channels.
2779 |
2780 |     result = ma_channel_converter_init(&config, NULL, &converter);
2781 |     if (result != MA_SUCCESS) {
2782 |         // Error.
2783 |     }
2784 |     ```
2785 |
2786 | To perform the conversion simply call `ma_channel_converter_process_pcm_frames()` like so:
2787 |
2788 |     ```c
2789 |     ma_result result = ma_channel_converter_process_pcm_frames(&converter, pFramesOut, pFramesIn,
> frameCount);
2790 |     if (result != MA_SUCCESS) {
2791 |         // Error.
2792 |     }
2793 |     ```
2794 |
2795 | It is up to the caller to ensure the output buffer is large enough to accommodate the new PCM
2796 | frames.
2797 |
2798 | Input and output PCM frames are always interleaved. Deinterleaved layouts are not supported.
2799 |
2800 |
2801 | 10.2.1. Channel Mapping
2802 | -----
2803 | In addition to converting from one channel count to another, like the example above, the channel
2804 | converter can also be used to rearrange channels. When initializing the channel converter, you can
2805 | optionally pass in channel maps for both the input and output frames. If the channel counts are the
2806 | same, and each channel map contains the same channel positions with the exception that they're in
2807 | a different order, a simple shuffling of the channels will be performed. If, however, there is not
2808 | a 1:1 mapping of channel positions, or the channel counts differ, the input channels will be mixed
2809 | based on a mixing mode which is specified when initializing the `ma_channel_converter_config`
2810 | object.
2811 |
2812 | When converting from mono to multi-channel, the mono channel is simply copied to each output
2813 | channel. When going the other way around, the audio of each output channel is simply averaged and
2814 | copied to the mono channel.
2815 |
2816 | In more complicated cases blending is used. The `ma_channel_mix_mode_simple` mode will drop excess
2817 | channels and silence extra channels. For example, converting from 4 to 2 channels, the 3rd and 4th
2818 | channels will be dropped, whereas converting from 2 to 4 channels will put silence into the 3rd and
2819 | 4th channels.
2820 |
2821 | The `ma_channel_mix_mode_rectangle` mode uses spacial locality based on a rectangle to compute a
2822 | simple distribution between input and output. Imagine sitting in the middle of a room, with
2823 | speakers on the walls representing channel positions. The `MA_CHANNEL_FRONT_LEFT` position can be
2824 | thought of as being in the corner of the front and left walls.
2825 |
2826 | Finally, the `ma_channel_mix_mode_custom_weights` mode can be used to use custom user-defined
2827 | weights. Custom weights can be passed in as the last parameter of
2828 | `ma_channel_converter_config_init()`.
2829 |
2830 | Predefined channel maps can be retrieved with `ma_channel_map_init_standard()`. This takes a
2831 | `ma_standard_channel_map` enum as its first parameter, which can be one of the following:
2832 |
2833 |
> +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
2834 | | Name                                     | Description
> |
2835 |

```

```

> +-----+
2836 | | ma_standard_channel_map_default | Default channel map used by miniaudio. See below.
> |
2837 | | ma_standard_channel_map_microsoft | Channel map used by Microsoft's bitfield channel maps.
> |
2838 | | ma_standard_channel_map_alsa | Default ALSA channel map.
> |
2839 | | ma_standard_channel_map_rfc3551 | RFC 3551. Based on AIFF.
> |
2840 | | ma_standard_channel_map_flac | FLAC channel map.
> |
2841 | | ma_standard_channel_map_vorbis | Vorbis channel map.
> |
2842 | | ma_standard_channel_map_sound4 | FreeBSD's sound(4).
> |
2843 | | ma_standard_channel_map_sndio | sndio channel map. http://www.sndio.org/tips.html.

> |
2845 |
> +-----+
2846 |
2847 | Below are the channel maps used by default in miniaudio (`ma_standard_channel_map_default`):
2848 |
2849 | +-----+
2850 | | Channel Count | Mapping |
2851 | +-----+
2852 | | 1 (Mono) | 0: MA_CHANNEL_MONO |
2853 | +-----+
2854 | | 2 (Stereo) | 0: MA_CHANNEL_FRONT_LEFT <br> |
2855 | | | 1: MA_CHANNEL_FRONT_RIGHT |
2856 | +-----+
2857 | | 3 | 0: MA_CHANNEL_FRONT_LEFT <br> |
2858 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2859 | | | 2: MA_CHANNEL_FRONT_CENTER |
2860 | +-----+
2861 | | 4 (Surround) | 0: MA_CHANNEL_FRONT_LEFT <br> |
2862 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2863 | | | 2: MA_CHANNEL_FRONT_CENTER <br> |
2864 | | | 3: MA_CHANNEL_BACK_CENTER |
2865 | +-----+
2866 | | 5 | 0: MA_CHANNEL_FRONT_LEFT <br> |
2867 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2868 | | | 2: MA_CHANNEL_FRONT_CENTER <br> |
2869 | | | 3: MA_CHANNEL_BACK_LEFT <br> |
2870 | | | 4: MA_CHANNEL_BACK_RIGHT |
2871 | +-----+
2872 | | 6 (5.1) | 0: MA_CHANNEL_FRONT_LEFT <br> |
2873 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2874 | | | 2: MA_CHANNEL_FRONT_CENTER <br> |
2875 | | | 3: MA_CHANNEL_LFE <br> |
2876 | | | 4: MA_CHANNEL_SIDE_LEFT <br> |
2877 | | | 5: MA_CHANNEL_SIDE_RIGHT |
2878 | +-----+
2879 | | 7 | 0: MA_CHANNEL_FRONT_LEFT <br> |
2880 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2881 | | | 2: MA_CHANNEL_FRONT_CENTER <br> |
2882 | | | 3: MA_CHANNEL_LFE <br> |
2883 | | | 4: MA_CHANNEL_BACK_CENTER <br> |
2884 | | | 4: MA_CHANNEL_SIDE_LEFT <br> |
2885 | | | 5: MA_CHANNEL_SIDE_RIGHT |
2886 | +-----+
2887 | | 8 (7.1) | 0: MA_CHANNEL_FRONT_LEFT <br> |
2888 | | | 1: MA_CHANNEL_FRONT_RIGHT <br> |
2889 | | | 2: MA_CHANNEL_FRONT_CENTER <br> |
2890 | | | 3: MA_CHANNEL_LFE <br> |
2891 | | | 4: MA_CHANNEL_BACK_LEFT <br> |
2892 | | | 5: MA_CHANNEL_BACK_RIGHT <br> |
2893 | | | 6: MA_CHANNEL_SIDE_LEFT <br> |
2894 | | | 7: MA_CHANNEL_SIDE_RIGHT |
2895 | +-----+
2896 | | Other | All channels set to 0. This |
2897 | | | is equivalent to the same |
2898 | | | mapping as the device. |
2899 | +-----+
2900 |
2901 |
2902 |
2903 | 10.3. Resampling

```

```

2904 | -----
2905 | Resampling is achieved with the `ma_resampler` object. To create a resampler object, do something
2906 | like the following:
2907 |
2908 |     ```c
2909 |     ma_resampler_config config = ma_resampler_config_init(
2910 |         ma_format_s16,
2911 |         channels,
2912 |         sampleRateIn,
2913 |         sampleRateOut,
2914 |         ma_resample_algorithm_linear);
2915 |
2916 |     ma_resampler resampler;
2917 |     ma_result result = ma_resampler_init(&config, NULL, &resampler);
2918 |     if (result != MA_SUCCESS) {
2919 |         // An error occurred...
2920 |     }
2921 |     ```
2922 |
2923 | Do the following to uninitialized the resampler:
2924 |
2925 |     ```c
2926 |     ma_resampler_uninit(&resampler);
2927 |     ```
2928 |
2929 | The following example shows how data can be processed
2930 |
2931 |     ```c
2932 |     ma_uint64 frameCountIn = 1000;
2933 |     ma_uint64 frameCountOut = 2000;
2934 |     ma_result result = ma_resampler_process_pcm_frames(&resampler, pFramesIn, &frameCountIn,
> pFramesOut, &frameCountOut);
2935 |     if (result != MA_SUCCESS) {
2936 |         // An error occurred...
2937 |     }
2938 |
2939 |     // At this point, frameCountIn contains the number of input frames that were consumed and
> frameCountOut contains the
2940 |     // number of output frames written.
2941 |     ```
2942 |
2943 | To initialize the resampler you first need to set up a config (`ma_resampler_config`) with
2944 | `ma_resampler_config_init()`. You need to specify the sample format you want to use, the number of
2945 | channels, the input and output sample rate, and the algorithm.
2946 |
2947 | The sample format can be either `ma_format_s16` or `ma_format_f32`. If you need a different format
2948 | you will need to perform pre- and post-conversions yourself where necessary. Note that the format
2949 | is the same for both input and output. The format cannot be changed after initialization.
2950 |
2951 | The resampler supports multiple channels and is always interleaved (both input and output). The
2952 | channel count cannot be changed after initialization.
2953 |
2954 | The sample rates can be anything other than zero, and are always specified in hertz. They should be
2955 | set to something like 44100, etc. The sample rate is the only configuration property that can be
2956 | changed after initialization.
2957 |
2958 | The miniaudio resampler has built-in support for the following algorithms:
2959 |
2960 |     +-----+-----+
2961 |     | Algorithm | Enum Token          |
2962 |     +-----+-----+
2963 |     | Linear    | ma_resample_algorithm_linear |
2964 |     | Custom    | ma_resample_algorithm_custom |
2965 |     +-----+-----+
2966 |
2967 | The algorithm cannot be changed after initialization.
2968 |
2969 | Processing always happens on a per PCM frame basis and always assumes interleaved input and output.
2970 | De-interleaved processing is not supported. To process frames, use
2971 | `ma_resampler_process_pcm_frames()`. On input, this function takes the number of output frames you
2972 | can fit in the output buffer and the number of input frames contained in the input buffer. On
2973 | output these variables contain the number of output frames that were written to the output buffer
2974 | and the number of input frames that were consumed in the process. You can pass in NULL for the
2975 | input buffer in which case it will be treated as an infinitely large buffer of zeros. The output
2976 | buffer can also be NULL, in which case the processing will be treated as seek.
2977 |
2978 | The sample rate can be changed dynamically on the fly. You can change this with explicit sample
2979 | rates with `ma_resampler_set_rate()` and also with a decimal ratio with
2980 | `ma_resampler_set_rate_ratio()`. The ratio is in/out.

```

```

2981 |
2982 | Sometimes it's useful to know exactly how many input frames will be required to output a specific
2983 | number of frames. You can calculate this with `ma_resampler_get_required_input_frame_count()`.
2984 | Likewise, it's sometimes useful to know exactly how many frames would be output given a certain
2985 | number of input frames. You can do this with `ma_resampler_get_expected_output_frame_count()`.
2986 |
2987 | Due to the nature of how resampling works, the resampler introduces some latency. This can be
2988 | retrieved in terms of both the input rate and the output rate with
2989 | `ma_resampler_get_input_latency()` and `ma_resampler_get_output_latency()`.
2990 |
2991 |
2992 | 10.3.1. Resampling Algorithms
2993 | -----
2994 | The choice of resampling algorithm depends on your situation and requirements.
2995 |
2996 |
2997 | 10.3.1.1. Linear Resampling
2998 | -----
2999 | The linear resampler is the fastest, but comes at the expense of poorer quality. There is, however,
3000 | some control over the quality of the linear resampler which may make it a suitable option depending
3001 | on your requirements.
3002 |
3003 | The linear resampler performs low-pass filtering before or after downsampling or upsampling,
3004 | depending on the sample rates you're converting between. When decreasing the sample rate, the
3005 | low-pass filter will be applied before downsampling. When increasing the rate it will be performed
3006 | after upsampling. By default a fourth order low-pass filter will be applied. This can be configured
3007 | via the `lpfOrder` configuration variable. Setting this to 0 will disable filtering.
3008 |
3009 | The low-pass filter has a cutoff frequency which defaults to half the sample rate of the lowest of
3010 | the input and output sample rates (Nyquist Frequency).
3011 |
3012 | The API for the linear resampler is the same as the main resampler API, only it's called
3013 | `ma_linear_resampler`.
3014 |
3015 |
3016 | 10.3.2. Custom Resamplers
3017 | -----
3018 | You can implement a custom resampler by using the `ma_resample_algorithm_custom` resampling
3019 | algorithm and setting a vtable in the resampler config:
3020 |
3021 |     ```c
3022 |     ma_resampler_config config = ma_resampler_config_init(..., ma_resample_algorithm_custom);
3023 |     config.pBackendVTable = &g_customResamplerVTable;
3024 |     ```
3025 |
3026 | Custom resamplers are useful if the stock algorithms are not appropriate for your use case. You
3027 | need to implement the required functions in `ma_resampling_backend_vtable`. Note that not all
3028 | functions in the vtable need to be implemented, but if it's possible to implement, they should be.
3029 |
3030 | You can use the `ma_linear_resampler` object for an example on how to implement the vtable. The
3031 | `onGetHeapSize` callback is used to calculate the size of any internal heap allocation the custom
3032 | resampler will need to make given the supplied config. When you initialize the resampler via the
3033 | `onInit` callback, you'll be given a pointer to a heap allocation which is where you should store
3034 | the heap allocated data. You should not free this data in `onUninit` because miniaudio will manage
3035 | it for you.
3036 |
3037 | The `onProcess` callback is where the actual resampling takes place. On input, `pFrameCountIn`
3038 | points to a variable containing the number of frames in the `pFramesIn` buffer and
3039 | `pFrameCountOut` points to a variable containing the capacity in frames of the `pFramesOut` buffer.
3040 | On output, `pFrameCountIn` should be set to the number of input frames that were fully consumed,
3041 | whereas `pFrameCountOut` should be set to the number of frames that were written to `pFramesOut`.
3042 |
3043 | The `onSetRate` callback is optional and is used for dynamically changing the sample rate. If
3044 | dynamic rate changes are not supported, you can set this callback to NULL.
3045 |
3046 | The `onGetInputLatency` and `onGetOutputLatency` functions are used for retrieving the latency in
3047 | input and output rates respectively. These can be NULL in which case latency calculations will be
3048 | assumed to be NULL.
3049 |
3050 | The `onGetRequiredInputFrameCount` callback is used to give miniaudio a hint as to how many input
3051 | frames are required to be available to produce the given number of output frames. Likewise, the
3052 | `onGetExpectedOutputFrameCount` callback is used to determine how many output frames will be
3053 | produced given the specified number of input frames. miniaudio will use these as a hint, but they
3054 | are optional and can be set to NULL if you're unable to implement them.
3055 |
3056 |
3057 |
3058 | 10.4. General Data Conversion
3059 | -----

```

```

3060 | The `ma_data_converter` API can be used to wrap sample format conversion, channel conversion and
3061 | resampling into one operation. This is what miniaudio uses internally to convert between the format
3062 | requested when the device was initialized and the format of the backend's native device. The API
3063 | for general data conversion is very similar to the resampling API. Create a `ma_data_converter`
3064 | object like this:
3065 |
3066 |     ```c
3067 |     ma_data_converter_config config = ma_data_converter_config_init(
3068 |         inputFormat,
3069 |         outputFormat,
3070 |         inputChannels,
3071 |         outputChannels,
3072 |         inputSampleRate,
3073 |         outputSampleRate
3074 |     );
3075 |
3076 |     ma_data_converter converter;
3077 |     ma_result result = ma_data_converter_init(&config, NULL, &converter);
3078 |     if (result != MA_SUCCESS) {
3079 |         // An error occurred...
3080 |     }
3081 |     ```
3082 |
3083 | In the example above we use `ma_data_converter_config_init()` to initialize the config, however
3084 | there's many more properties that can be configured, such as channel maps and resampling quality.
3085 | Something like the following may be more suitable depending on your requirements:
3086 |
3087 |     ```c
3088 |     ma_data_converter_config config = ma_data_converter_config_init_default();
3089 |     config.formatIn = inputFormat;
3090 |     config.formatOut = outputFormat;
3091 |     config.channelsIn = inputChannels;
3092 |     config.channelsOut = outputChannels;
3093 |     config.sampleRateIn = inputSampleRate;
3094 |     config.sampleRateOut = outputSampleRate;
3095 |     ma_channel_map_init_standard(ma_standard_channel_map_flac, config.channelMapIn,
> sizeof(config.channelMapIn)/sizeof(config.channelMapIn[0]), config.channelCountIn);
3096 |     config.resampling.linear.lpfOrder = MA_MAX_FILTER_ORDER;
3097 |     ```
3098 |
3099 | Do the following to uninitialized the data converter:
3100 |
3101 |     ```c
3102 |     ma_data_converter_uninit(&converter, NULL);
3103 |     ```
3104 |
3105 | The following example shows how data can be processed
3106 |
3107 |     ```c
3108 |     ma_uint64 frameCountIn = 1000;
3109 |     ma_uint64 frameCountOut = 2000;
3110 |     ma_result result = ma_data_converter_process_pcm_frames(&converter, pFramesIn, &frameCountIn,
> pFramesOut, &frameCountOut);
3111 |     if (result != MA_SUCCESS) {
3112 |         // An error occurred...
3113 |     }
3114 |
3115 |     // At this point, frameCountIn contains the number of input frames that were consumed and
> frameCountOut contains the number
3116 |     // of output frames written.
3117 |     ```
3118 |
3119 | The data converter supports multiple channels and is always interleaved (both input and output).
3120 | The channel count cannot be changed after initialization.
3121 |
3122 | Sample rates can be anything other than zero, and are always specified in hertz. They should be set
3123 | to something like 44100, etc. The sample rate is the only configuration property that can be
3124 | changed after initialization, but only if the `resampling.allowDynamicSampleRate` member of
3125 | `ma_data_converter_config` is set to `MA_TRUE`. To change the sample rate, use
3126 | `ma_data_converter_set_rate()` or `ma_data_converter_set_rate_ratio()`. The ratio must be in/out.
3127 | The resampling algorithm cannot be changed after initialization.
3128 |
3129 | Processing always happens on a per PCM frame basis and always assumes interleaved input and output.
3130 | De-interleaved processing is not supported. To process frames, use
3131 | `ma_data_converter_process_pcm_frames()`. On input, this function takes the number of output frames
3132 | you can fit in the output buffer and the number of input frames contained in the input buffer. On
3133 | output these variables contain the number of output frames that were written to the output buffer
3134 | and the number of input frames that were consumed in the process. You can pass in NULL for the
3135 | input buffer in which case it will be treated as an infinitely large

```

```

3136 | buffer of zeros. The output buffer can also be NULL, in which case the processing will be treated
3137 | as seek.
3138 |
3139 | Sometimes it's useful to know exactly how many input frames will be required to output a specific
3140 | number of frames. You can calculate this with `ma_data_converter_get_required_input_frame_count()`.
3141 | Likewise, it's sometimes useful to know exactly how many frames would be output given a certain
3142 | number of input frames. You can do this with `ma_data_converter_get_expected_output_frame_count()`.
3143 |
3144 | Due to the nature of how resampling works, the data converter introduces some latency if resampling
3145 | is required. This can be retrieved in terms of both the input rate and the output rate with
3146 | `ma_data_converter_get_input_latency()` and `ma_data_converter_get_output_latency()`.
3147 |
3148 |
3149 |
3150 | 11. Filtering
3151 | =====
3152 |
3153 | 11.1. Biquad Filtering
3154 | -----
3155 | Biquad filtering is achieved with the `ma_biquad` API. Example:
3156 |
3157 | ```c
3158 | ma_biquad_config config = ma_biquad_config_init(ma_format_f32, channels, b0, b1, b2, a0, a1,
> a2);
3159 | ma_result result = ma_biquad_init(&config, NULL, &biquad);
3160 | if (result != MA_SUCCESS) {
3161 |     // Error.
3162 | }
3163 |
3164 | ...
3165 |
3166 | ma_biquad_process_pcm_frames(&biquad, pFramesOut, pFramesIn, frameCount);
3167 | ```
3168 |
3169 | Biquad filtering is implemented using transposed direct form 2. The numerator coefficients are b0,
3170 | b1 and b2, and the denominator coefficients are a0, a1 and a2. The a0 coefficient is required and
3171 | coefficients must not be pre-normalized.
3172 |
3173 | Supported formats are `ma_format_s16` and `ma_format_f32`. If you need to use a different format
3174 | you need to convert it yourself beforehand. When using `ma_format_s16` the biquad filter will use
3175 | fixed point arithmetic. When using `ma_format_f32`, floating point arithmetic will be used.
3176 |
3177 | Input and output frames are always interleaved.
3178 |
3179 | Filtering can be applied in-place by passing in the same pointer for both the input and output
3180 | buffers, like so:
3181 |
3182 | ```c
3183 | ma_biquad_process_pcm_frames(&biquad, pMyData, pMyData, frameCount);
3184 | ```
3185 |
3186 | If you need to change the values of the coefficients, but maintain the values in the registers you
3187 | can do so with `ma_biquad_reinit()`. This is useful if you need to change the properties of the
3188 | filter while keeping the values of registers valid to avoid glitching. Do not use
3189 | `ma_biquad_init()` for this as it will do a full initialization which involves clearing the
3190 | registers to 0. Note that changing the format or channel count after initialization is invalid and
3191 | will result in an error.
3192 |
3193 |
3194 | 11.2. Low-Pass Filtering
3195 | -----
3196 | Low-pass filtering is achieved with the following APIs:
3197 |
3198 | +-----+-----+
3199 | | API      | Description |
3200 | +-----+-----+
3201 | | ma_lpf1 | First order low-pass filter |
3202 | | ma_lpf2 | Second order low-pass filter |
3203 | | ma_lpf  | High order low-pass filter (Butterworth) |
3204 | +-----+-----+
3205 |
3206 | Low-pass filter example:
3207 |
3208 | ```c
3209 | ma_lpf_config config = ma_lpf_config_init(ma_format_f32, channels, sampleRate, cutoffFrequency,
> order);
3210 | ma_result result = ma_lpf_init(&config, &lpf);
3211 | if (result != MA_SUCCESS) {
3212 |     // Error.

```

```

3213 |     }
3214 |
3215 |     ...
3216 |
3217 |     ma_lpf_process_pcm_frames(&lpf, pFramesOut, pFramesIn, frameCount);
3218 |     ...
3219 |
3220 | Supported formats are `ma_format_s16` and `ma_format_f32`. If you need to use a different format
3221 | you need to convert it yourself beforehand. Input and output frames are always interleaved.
3222 |
3223 | Filtering can be applied in-place by passing in the same pointer for both the input and output
3224 | buffers, like so:
3225 |
3226 |     ```c
3227 |     ma_lpf_process_pcm_frames(&lpf, pMyData, pMyData, frameCount);
3228 |     ...
3229 |
3230 | The maximum filter order is limited to `MA_MAX_FILTER_ORDER` which is set to 8. If you need more,
3231 | you can chain first and second order filters together.
3232 |
3233 |     ```c
3234 |     for (iFilter = 0; iFilter < filterCount; iFilter += 1) {
3235 |         ma_lpf2_process_pcm_frames(&lpf2[iFilter], pMyData, pMyData, frameCount);
3236 |     }
3237 |     ...
3238 |
3239 | If you need to change the configuration of the filter, but need to maintain the state of internal
3240 | registers you can do so with `ma_lpf_reinit()`. This may be useful if you need to change the sample
3241 | rate and/or cutoff frequency dynamically while maintaining smooth transitions. Note that changing
3242 | > the
3243 | format or channel count after initialization is invalid and will result in an error.
3244 |
3245 | The `ma_lpf` object supports a configurable order, but if you only need a first order filter you
3246 | may want to consider using `ma_lpf1`. Likewise, if you only need a second order filter you can use
3247 | `ma_lpf2`. The advantage of this is that they're lighter weight and a bit more efficient.
3248 |
3249 | If an even filter order is specified, a series of second order filters will be processed in a
3250 | chain. If an odd filter order is specified, a first order filter will be applied, followed by a
3251 | series of second order filters in a chain.
3252 |
3253 | 11.3. High-Pass Filtering
3254 | -----
3255 | High-pass filtering is achieved with the following APIs:
3256 |
3257 | +-----+-----+
3258 | | API      | Description |
3259 | +-----+-----+
3260 | | ma_hpf1  | First order high-pass filter |
3261 | | ma_hpf2  | Second order high-pass filter |
3262 | | ma_hpf   | High order high-pass filter (Butterworth) |
3263 | +-----+-----+
3264 |
3265 | High-pass filters work exactly the same as low-pass filters, only the APIs are called `ma_hpf1`,
3266 | `ma_hpf2` and `ma_hpf`. See example code for low-pass filters for example usage.
3267 |
3268 |
3269 | 11.4. Band-Pass Filtering
3270 | -----
3271 | Band-pass filtering is achieved with the following APIs:
3272 |
3273 | +-----+-----+
3274 | | API      | Description |
3275 | +-----+-----+
3276 | | ma_bpf2  | Second order band-pass filter |
3277 | | ma_bpf   | High order band-pass filter   |
3278 | +-----+-----+
3279 |
3280 | Band-pass filters work exactly the same as low-pass filters, only the APIs are called `ma_bpf2` and
3281 | `ma_bpf`. See example code for low-pass filters for example usage. Note that the order for
3282 | band-pass filters must be an even number which means there is no first order band-pass filter,
3283 | unlike low-pass and high-pass filters.
3284 |
3285 |
3286 | 11.5. Notch Filtering
3287 | -----
3288 | Notch filtering is achieved with the following APIs:
3289 |
3290 | +-----+-----+

```

```

3291 | | API      | Description |
3292 | +-----+-----+
3293 | | ma_notch2 | Second order notching filter |
3294 | +-----+-----+
3295 |
3296 |
3297 | 11.6. Peaking EQ Filtering
3298 | -----
3299 | Peaking filtering is achieved with the following APIs:
3300 |
3301 | +-----+-----+
3302 | | API      | Description |
3303 | +-----+-----+
3304 | | ma_peak2  | Second order peaking filter |
3305 | +-----+-----+
3306 |
3307 |
3308 | 11.7. Low Shelf Filtering
3309 | -----
3310 | Low shelf filtering is achieved with the following APIs:
3311 |
3312 | +-----+-----+
3313 | | API      | Description |
3314 | +-----+-----+
3315 | | ma_loshelf2 | Second order low shelf filter |
3316 | +-----+-----+
3317 |
3318 | Where a high-pass filter is used to eliminate lower frequencies, a low shelf filter can be used to
3319 | just turn them down rather than eliminate them entirely.
3320 |
3321 |
3322 | 11.8. High Shelf Filtering
3323 | -----
3324 | High shelf filtering is achieved with the following APIs:
3325 |
3326 | +-----+-----+
3327 | | API      | Description |
3328 | +-----+-----+
3329 | | ma_hishelf2 | Second order high shelf filter |
3330 | +-----+-----+
3331 |
3332 | The high shelf filter has the same API as the low shelf filter, only you would use `ma_hishelf`
3333 | instead of `ma_loshelf`. Where a low shelf filter is used to adjust the volume of low frequencies,
3334 | the high shelf filter does the same thing for high frequencies.
3335 |
3336 |
3337 |
3338 |
3339 | 12. Waveform and Noise Generation
3340 | =====
3341 |
3342 | 12.1. Waveforms
3343 | -----
3344 | miniaudio supports generation of sine, square, triangle and sawtooth waveforms. This is achieved
3345 | with the `ma_waveform` API. Example:
3346 |
3347 | ```c
3348 | ma_waveform_config config = ma_waveform_config_init(
3349 |     FORMAT,
3350 |     CHANNELS,
3351 |     SAMPLE_RATE,
3352 |     ma_waveform_type_sine,
3353 |     amplitude,
3354 |     frequency);
3355 |
3356 | ma_waveform waveform;
3357 | ma_result result = ma_waveform_init(&config, &waveform);
3358 | if (result != MA_SUCCESS) {
3359 |     // Error.
3360 | }
3361 |
3362 | ...
3363 |
3364 | ma_waveform_read_pcm_frames(&waveform, pOutput, frameCount);
3365 | ```
3366 |
3367 | The amplitude, frequency, type, and sample rate can be changed dynamically with
3368 | `ma_waveform_set_amplitude()`, `ma_waveform_set_frequency()`, `ma_waveform_set_type()`, and
3369 | `ma_waveform_set_sample_rate()` respectively.

```

```

3370 |
3371 | You can invert the waveform by setting the amplitude to a negative value. You can use this to
3372 | control whether or not a sawtooth has a positive or negative ramp, for example.
3373 |
3374 | Below are the supported waveform types:
3375 |
3376 | +-----+
3377 | | Enum Name |
3378 | +-----+
3379 | | ma_waveform_type_sine |
3380 | | ma_waveform_type_square |
3381 | | ma_waveform_type_triangle |
3382 | | ma_waveform_type_sawtooth |
3383 | +-----+
3384 |
3385 |
3386 |
3387 | 12.2. Noise
3388 | -----
3389 | miniaudio supports generation of white, pink and Brownian noise via the `ma_noise` API. Example:
3390 |
3391 | ```c
3392 |     ma_noise_config config = ma_noise_config_init(
3393 |         FORMAT,
3394 |         CHANNELS,
3395 |         ma_noise_type_white,
3396 |         SEED,
3397 |         amplitude);
3398 |
3399 |     ma_noise noise;
3400 |     ma_result result = ma_noise_init(&config, &noise);
3401 |     if (result != MA_SUCCESS) {
3402 |         // Error.
3403 |     }
3404 |
3405 |     ...
3406 |
3407 |     ma_noise_read_pcm_frames(&noise, pOutput, frameCount);
3408 | ```
3409 |
3410 | The noise API uses simple LCG random number generation. It supports a custom seed which is useful
3411 | for things like automated testing requiring reproducibility. Setting the seed to zero will default
3412 | to `MA_DEFAULT_LCG_SEED`.
3413 |
3414 | The amplitude and seed can be changed dynamically with `ma_noise_set_amplitude()` and
3415 | `ma_noise_set_seed()` respectively.
3416 |
3417 | By default, the noise API will use different values for different channels. So, for example, the
3418 | left side in a stereo stream will be different to the right side. To instead have each channel use
3419 | the same random value, set the `duplicateChannels` member of the noise config to true, like so:
3420 |
3421 | ```c
3422 |     config.duplicateChannels = MA_TRUE;
3423 | ```
3424 |
3425 | Below are the supported noise types.
3426 |
3427 | +-----+
3428 | | Enum Name |
3429 | +-----+
3430 | | ma_noise_type_white |
3431 | | ma_noise_type_pink |
3432 | | ma_noise_type_brownian |
3433 | +-----+
3434 |
3435 |
3436 |
3437 | 13. Audio Buffers
3438 | =====
3439 | miniaudio supports reading from a buffer of raw audio data via the `ma_audio_buffer` API. This can
3440 | read from memory that's managed by the application, but can also handle the memory management for
3441 | you internally. Memory management is flexible and should support most use cases.
3442 |
3443 | Audio buffers are initialized using the standard configuration system used everywhere in miniaudio:
3444 |
3445 | ```c
3446 |     ma_audio_buffer_config config = ma_audio_buffer_config_init(
3447 |         format,
3448 |         channels,

```

```

3449 |         sizeInFrames,
3450 |         pExistingData,
3451 |         &allocationCallbacks);
3452 |
3453 |     ma_audio_buffer buffer;
3454 |     result = ma_audio_buffer_init(&config, &buffer);
3455 |     if (result != MA_SUCCESS) {
3456 |         // Error.
3457 |     }
3458 |
3459 |     ...
3460 |
3461 |     ma_audio_buffer_uninit(&buffer);
3462 |     ...
3463 |
3464 | In the example above, the memory pointed to by `pExistingData` will *not* be copied and is how an
3465 | application can do self-managed memory allocation. If you would rather make a copy of the data, use
3466 | `ma_audio_buffer_init_copy()`. To uninitialized the buffer, use `ma_audio_buffer_uninit()`.
3467 |
3468 | Sometimes it can be convenient to allocate the memory for the `ma_audio_buffer` structure and the
3469 | raw audio data in a contiguous block of memory. That is, the raw audio data will be located
3470 | immediately after the `ma_audio_buffer` structure. To do this, use
3471 | `ma_audio_buffer_alloc_and_init()`:
3472 |
3473 |     ```c
3474 |     ma_audio_buffer_config config = ma_audio_buffer_config_init(
3475 |         format,
3476 |         channels,
3477 |         sizeInFrames,
3478 |         pExistingData,
3479 |         &allocationCallbacks);
3480 |
3481 |     ma_audio_buffer* pBuffer
3482 |     result = ma_audio_buffer_alloc_and_init(&config, &pBuffer);
3483 |     if (result != MA_SUCCESS) {
3484 |         // Error
3485 |     }
3486 |
3487 |     ...
3488 |
3489 |     ma_audio_buffer_uninit_and_free(&buffer);
3490 |     ...
3491 |
3492 | If you initialize the buffer with `ma_audio_buffer_alloc_and_init()` you should uninitialized it
3493 | with `ma_audio_buffer_uninit_and_free()`. In the example above, the memory pointed to by
3494 | `pExistingData` will be copied into the buffer, which is contrary to the behavior of
3495 | `ma_audio_buffer_init()`.
3496 |
3497 | An audio buffer has a playback cursor just like a decoder. As you read frames from the buffer, the
3498 | cursor moves forward. The last parameter (`loop`) can be used to determine if the buffer should
3499 | loop. The return value is the number of frames actually read. If this is less than the number of
3500 | frames requested it means the end has been reached. This should never happen if the `loop`
3501 | parameter is set to true. If you want to manually loop back to the start, you can do so with with
3502 | `ma_audio_buffer_seek_to_pcm_frame(pAudioBuffer, 0)`. Below is an example for reading data from an
3503 | audio buffer.
3504 |
3505 |     ```c
3506 |     ma_uint64 framesRead = ma_audio_buffer_read_pcm_frames(pAudioBuffer, pFramesOut,
3507 | > desiredFrameCount, isLooping);
3508 |     if (framesRead < desiredFrameCount) {
3509 |         // If not looping, this means the end has been reached. This should never happen in looping
3510 | > mode with valid input.
3511 |     }
3512 |     ...
3513 |
3514 | Sometimes you may want to avoid the cost of data movement between the internal buffer and the
3515 | output buffer. Instead you can use memory mapping to retrieve a pointer to a segment of data:
3516 |
3517 |     ```c
3518 |     void* pMappedFrames;
3519 |     ma_uint64 frameCount = frameCountToTryMapping;
3520 |     ma_result result = ma_audio_buffer_map(pAudioBuffer, &pMappedFrames, &frameCount);
3521 |     if (result == MA_SUCCESS) {
3522 |         // Map was successful. The value in frameCount will be how many frames were _actually_
3523 | > mapped, which may be
3524 |         // less due to the end of the buffer being reached.
3525 |         ma_copy_pcm_frames(pFramesOut, pMappedFrames, frameCount, pAudioBuffer->format,
3526 | > pAudioBuffer->channels);
3527 |     }
3528 |     ...

```

```

3524 |         // You must unmap the buffer.
3525 |         ma_audio_buffer_unmap(pAudioBuffer, frameCount);
3526 |     }
3527 |     ...
3528 |
3529 | When you use memory mapping, the read cursor is increment by the frame count passed in to
3530 | `ma_audio_buffer_unmap()`. If you decide not to process every frame you can pass in a value smaller
3531 | than the value returned by `ma_audio_buffer_map()`. The disadvantage to using memory mapping is
3532 | that it does not handle looping for you. You can determine if the buffer is at the end for the
3533 | purpose of looping with `ma_audio_buffer_at_end()` or by inspecting the return value of
3534 | `ma_audio_buffer_unmap()` and checking if it equals `MA_AT_END`. You should not treat `MA_AT_END`
3535 | as an error when returned by `ma_audio_buffer_unmap()`.
3536 |
3537 |
3538 |
3539 | 14. Ring Buffers
3540 | =====
3541 | miniaudio supports lock free (single producer, single consumer) ring buffers which are exposed via
3542 | the `ma_rb` and `ma_pcm_rb` APIs. The `ma_rb` API operates on bytes, whereas the `ma_pcm_rb`
3543 | operates on PCM frames. They are otherwise identical as `ma_pcm_rb` is just a wrapper around
3544 | `ma_rb`.
3545 |
3546 | Unlike most other APIs in miniaudio, ring buffers support both interleaved and deinterleaved
3547 | streams. The caller can also allocate their own backing memory for the ring buffer to use
3548 | internally for added flexibility. Otherwise the ring buffer will manage it's internal memory for
3549 | you.
3550 |
3551 | The examples below use the PCM frame variant of the ring buffer since that's most likely the one
3552 | you will want to use. To initialize a ring buffer, do something like the following:
3553 |
3554 |     ```c
3555 |     ma_pcm_rb rb;
3556 |     ma_result result = ma_pcm_rb_init(FORMAT, CHANNELS, BUFFER_SIZE_IN_FRAMES, NULL, NULL, &rb);
3557 |     if (result != MA_SUCCESS) {
3558 |         // Error
3559 |     }
3560 |     ...
3561 |
3562 | The `ma_pcm_rb_init()` function takes the sample format and channel count as parameters because
3563 | it's the PCM variant of the ring buffer API. For the regular ring buffer that operates on bytes you
3564 | would call `ma_rb_init()` which leaves these out and just takes the size of the buffer in bytes
3565 | instead of frames. The fourth parameter is an optional pre-allocated buffer and the fifth parameter
3566 | is a pointer to a `ma_allocation_callbacks` structure for custom memory allocation routines.
3567 | Passing in `NULL` for this results in `MA_MALLOC()` and `MA_FREE()` being used.
3568 |
3569 | Use `ma_pcm_rb_init_ex()` if you need a deinterleaved buffer. The data for each sub-buffer is
3570 | offset from each other based on the stride. To manage your sub-buffers you can use
3571 | `ma_pcm_rb_get_subbuffer_stride()`, `ma_pcm_rb_get_subbuffer_offset()` and
3572 | `ma_pcm_rb_get_subbuffer_ptr()`.
3573 |
3574 | Use `ma_pcm_rb_acquire_read()` and `ma_pcm_rb_acquire_write()` to retrieve a pointer to a section
3575 | of the ring buffer. You specify the number of frames you need, and on output it will set to what
3576 | was actually acquired. If the read or write pointer is positioned such that the number of frames
3577 | requested will require a loop, it will be clamped to the end of the buffer. Therefore, the number
3578 | of frames you're given may be less than the number you requested.
3579 |
3580 | After calling `ma_pcm_rb_acquire_read()` or `ma_pcm_rb_acquire_write()`, you do your work on the
3581 | buffer and then "commit" it with `ma_pcm_rb_commit_read()` or `ma_pcm_rb_commit_write()`. This is
3582 | where the read/write pointers are updated. When you commit you need to pass in the buffer that was
3583 | returned by the earlier call to `ma_pcm_rb_acquire_read()` or `ma_pcm_rb_acquire_write()` and is
3584 | only used for validation. The number of frames passed to `ma_pcm_rb_commit_read()` and
3585 | `ma_pcm_rb_commit_write()` is what's used to increment the pointers, and can be less than what was
3586 | originally requested.
3587 |
3588 | If you want to correct for drift between the write pointer and the read pointer you can use a
3589 | combination of `ma_pcm_rb_pointer_distance()`, `ma_pcm_rb_seek_read()` and
3590 | `ma_pcm_rb_seek_write()`. Note that you can only move the pointers forward, and you should only
3591 | move the read pointer forward via the consumer thread, and the write pointer forward by the
3592 | producer thread. If there is too much space between the pointers, move the read pointer forward. If
3593 | there is too little space between the pointers, move the write pointer forward.
3594 |
3595 | You can use a ring buffer at the byte level instead of the PCM frame level by using the `ma_rb`
3596 | API. This is exactly the same, only you will use the `ma_rb` functions instead of `ma_pcm_rb` and
3597 | instead of frame counts you will pass around byte counts.
3598 |
3599 | The maximum size of the buffer in bytes is `0x7FFFFFFF-(MA_SIMD_ALIGNMENT-1)` due to the most
3600 | significant bit being used to encode a loop flag and the internally managed buffers always being
3601 | aligned to `MA_SIMD_ALIGNMENT`.
3602 |

```

```

3603 | Note that the ring buffer is only thread safe when used by a single consumer thread and single
3604 | producer thread.
3605 |
3606 |
3607 |
3608 | 15. Backends
3609 | =====
3610 | The following backends are supported by miniaudio. These are listed in order of default priority.
3611 | When no backend is specified when initializing a context or device, miniaudio will attempt to use
3612 | each of these backends in the order listed in the table below.
3613 |
3614 | Note that backends that are not usable by the build target will not be included in the build. For
3615 | example, ALSA, which is specific to Linux, will not be included in the Windows build.
3616 |
3617 | +-----+-----+-----+
3618 | | Name | Enum Name | Supported Operating Systems |
3619 | +-----+-----+-----+
3620 | | WASAPI | ma_backend_wasapi | Windows Vista+ |
3621 | | DirectSound | ma_backend_dsound | Windows XP+ |
3622 | | WinMM | ma_backend_winmm | Windows 95+ |
3623 | | Core Audio | ma_backend_coreaudio | macOS, iOS |
3624 | | sndio | ma_backend_sndio | OpenBSD |
3625 | | audio(4) | ma_backend_audio4 | NetBSD, OpenBSD |
3626 | | OSS | ma_backend_oss | FreeBSD |
3627 | | PulseAudio | ma_backend_pulseaudio | Cross Platform (disabled on Windows, BSD and Android) |
3628 | | ALSA | ma_backend_alsa | Linux |
3629 | | JACK | ma_backend_jack | Cross Platform (disabled on BSD and Android) |
3630 | | AAudio | ma_backend_aaudio | Android 8+ |
3631 | | OpenSL ES | ma_backend_opensl | Android (API level 16+) |
3632 | | Web Audio | ma_backend_webaudio | Web (via Emscripten) |
3633 | | Custom | ma_backend_custom | Cross Platform |
3634 | | Null | ma_backend_null | Cross Platform (not used on Web) |
3635 | +-----+-----+-----+
3636 |
3637 | Some backends have some nuance details you may want to be aware of.
3638 |
3639 | 15.1. WASAPI
3640 | -----
3641 | - Low-latency shared mode will be disabled when using an application-defined sample rate which is
3642 | different to the device's native sample rate. To work around this, set `wasapi.noAutoConvertSRC`
3643 | to true in the device config. This is due to IAudioClient3_InitializeSharedAudioStream() failing
3644 | when the AUDCLNT_STREAMFLAGS_AUTOCONVERTPCM flag is specified. Setting wasapi.noAutoConvertSRC
3645 | will result in miniaudio's internal resampler being used instead which will in turn enable the
3646 | use of low-latency shared mode.
3647 |
3648 | 15.2. PulseAudio
3649 | -----
3650 | - If you experience bad glitching/noise on Arch Linux, consider this fix from the Arch wiki:
3651 | https://wiki.archlinux.org/index.php/PulseAudio/Troubleshooting#Glitches,\_skips\_or\_crackling.
3652 | Alternatively, consider using a different backend such as ALSA.
3653 |
3654 | 15.3. Android
3655 | -----
3656 | - To capture audio on Android, remember to add the RECORD_AUDIO permission to your manifest:
3657 | <uses-permission android:name="android.permission.RECORD_AUDIO" />
3658 | - With OpenSL|ES, only a single ma_context can be active at any given time. This is due to a
3659 | limitation with OpenSL|ES.
3660 | - With AAudio, only default devices are enumerated. This is due to AAudio not having an enumeration
3661 | API (devices are enumerated through Java). You can however perform your own device enumeration
3662 | through Java and then set the ID in the ma_device_id structure (ma_device_id.aaudio) and pass it
3663 | to ma_device_init().
3664 | - The backend API will perform resampling where possible. The reason for this as opposed to using
3665 | miniaudio's built-in resampler is to take advantage of any potential device-specific
3666 | optimizations the driver may implement.
3667 |
3668 | BSD
3669 | ---
3670 | - The sndio backend is currently only enabled on OpenBSD builds.
3671 | - The audio(4) backend is supported on OpenBSD, but you may need to disable sndiod before you can
3672 | use it.
3673 |
3674 | 15.4. UWP
3675 | -----
3676 | - UWP only supports default playback and capture devices.
3677 | - UWP requires the Microphone capability to be enabled in the application's manifest
3678 | > (Package.appxmanifest):
3679 | <<<
3680 | <Package ...>

```

```

3681 |     ...
3682 |     <Capabilities>
3683 |         <DeviceCapability Name="microphone" />
3684 |     </Capabilities>
3685 | </Package>
3686 |     ...
3687 |
3688 | 15.5. Web Audio / Emscripten
3689 | -----
3690 | - You cannot use `std=c` compiler flags, nor `ansi`. This only applies to the Emscripten build.
3691 | - The first time a context is initialized it will create a global object called "miniaudio" whose
3692 |   primary purpose is to act as a factory for device objects.
3693 | - Currently the Web Audio backend uses ScriptProcessorNode's, but this may need to change later as
3694 |   they've been deprecated.
3695 | - Google has implemented a policy in their browsers that prevent automatic media output without
3696 |   first receiving some kind of user input. The following web page has additional details:
3697 |   https://developers.google.com/web/updates/2017/09/autoplay-policy-changes. Starting the device
3698 |   may fail if you try to start playback without first handling some kind of user input.
3699 |
3700 |
3701 |
3702 | 16. Optimization Tips
3703 | =====
3704 | See below for some tips on improving performance.
3705 |
3706 | 16.1. Low Level API
3707 | -----
3708 | - In the data callback, if your data is already clipped prior to copying it into the output buffer,
3709 |   set the `noClip` config option in the device config to true. This will disable miniaudio's built
3710 |   in clipping function.
3711 | - By default, miniaudio will pre-silence the data callback's output buffer. If you know that you
3712 |   will always write valid data to the output buffer you can disable pre-silencing by setting the
3713 |   `noPreSilence` config option in the device config to true.
3714 |
3715 | 16.2. High Level API
3716 | -----
3717 | - If a sound does not require doppler or pitch shifting, consider disabling pitching by
3718 |   initializing the sound with the `MA_SOUND_FLAG_NO_PITCH` flag.
3719 | - If a sound does not require spatialization, disable it by initializing the sound with the
3720 |   `MA_SOUND_FLAG_NO_SPATIALIZATION` flag. It can be re-enabled again post-initialization with
3721 |   `ma_sound_set_spatialization_enabled()`.
3722 | - If you know all of your sounds will always be the same sample rate, set the engine's sample
3723 |   rate to match that of the sounds. Likewise, if you're using a self-managed resource manager,
3724 |   consider setting the decoded sample rate to match your sounds. By configuring everything to
3725 |   use a consistent sample rate, sample rate conversion can be avoided.
3726 |
3727 |
3728 |
3729 | 17. Miscellaneous Notes
3730 | =====
3731 | - Automatic stream routing is enabled on a per-backend basis. Support is explicitly enabled for
3732 |   WASAPI and Core Audio, however other backends such as PulseAudio may naturally support it, though
3733 |   not all have been tested.
3734 | - When compiling with VC6 and earlier, decoding is restricted to files less than 2GB in size. This
3735 |   is due to 64-bit file APIs not being available.

4391 | Atomics.
4392 |
4393 | These are typesafe structures to prevent errors as a result of forgetting to reference variables
> atomically. It's too
4394 | easy to introduce subtle bugs where you accidentally do a regular assignment instead of an atomic
> load/store, etc. By
4395 | using a struct we can enforce the use of atomics at compile time.
4396 |
4397 | These types are declared in the header section because we need to reference them in structs below,
> but functions for
4398 | using them are only exposed in the implementation section. I do not want these to be part of the
> public API.
4399 |
4400 | There's a few downsides to this system. The first is that you need to declare a new struct for each
> type. Below are
4401 | some macros to help with the declarations. They will be named like so:
4402 |
4403 |     ma_atomic_uint32 - atomic ma_uint32
4404 |     ma_atomic_int32  - atomic ma_int32
4405 |     ma_atomic_uint64 - atomic ma_uint64
4406 |     ma_atomic_float  - atomic float
4407 |     ma_atomic_bool32 - atomic ma_bool32
4408 |
4409 | The other downside is that atomic pointers are extremely messy. You need to declare a new struct for
> each specific
4410 | type of pointer you need to make atomic. For example, an atomic ma_node* will look like this:
4411 |
4412 |     MA_ATOMIC_SAFE_TYPE_IMPL_PTR(node)
4413 |
4414 | Which will declare a type struct that's named like so:
4415 |
4416 |     ma_atomic_ptr_node
4417 |
4418 | Functions to use the atomic types are declared in the implementation section. All atomic functions
> are prefixed with
4419 | the name of the struct. For example:
4420 |
4421 |     ma_atomic_uint32_set() - Atomic store of ma_uint32
4422 |     ma_atomic_uint32_get() - Atomic load of ma_uint32
4423 |     etc.
4424 |
4425 | For pointer types it's the same, which makes them a bit messy to use due to the length of each
> function name, but in
4426 | return you get type safety and enforcement of atomic operations.
4427 | */

5457 | Converts the given input data.
5458 |
5459 | Both the input and output frames must be in the format specified in the config when the resampler
> was initialized.
5460 |
5461 | On input, [pFrameCountOut] contains the number of output frames to process. On output it contains
> the number of output frames that
5462 | were actually processed, which may be less than the requested amount which will happen if there's
> not enough input data. You can use
5463 | ma_resampler_get_expected_output_frame_count() to know how many output frames will be processed for
> a given number of input frames.
5464 |
5465 | On input, [pFrameCountIn] contains the number of input frames contained in [pFramesIn]. On output it
> contains the number of whole
5466 | input frames that were actually processed. You can use ma_resampler_get_required_input_frame_count()
> to know how many input frames
5467 | you should provide for a given number of output frames. [pFramesIn] can be NULL, in which case
> zeroes will be used instead.
5468 |
5469 | If [pFramesOut] is NULL, a seek is performed. In this case, if [pFrameCountOut] is not NULL it will
> seek by the specified number of
5470 | output frames. Otherwise, if [pFramesCountOut] is NULL and [pFrameCountIn] is not NULL, it will seek
> by the specified number of input
5471 | frames. When seeking, [pFramesIn] is allowed to NULL, in which case the internal timing state will
> be updated, but no input will be
5472 | processed. In this case, any internal filter state will be updated as if zeroes were passed in.
5473 |
5474 | It is an error for [pFramesOut] to be non-NULL and [pFrameCountOut] to be NULL.
5475 |
5476 | It is an error for both [pFrameCountOut] and [pFrameCountIn] to be NULL.

6806 |             int _unused;
6807 |         } interruption;
6808 |     } data;
6809 | } ma_device_notification;
6810 |
6811 | /*
6812 | The notification callback for when the application should be notified of a change to the device.
6813 |
6814 | This callback is used for notifying the application of changes such as when the device has started,
6815 | stopped, rerouted or an interruption has occurred. Note that not all backends will post all
6816 | notification types. For example, some backends will perform automatic stream routing without any
6817 | kind of notification to the host program which means miniaudio will never know about it and will

```

```

6818 | never be able to fire the rerouted notification. You should keep this in mind when designing your
6819 | program.
6820 |
6821 | The stopped notification will *not* get fired when a device is rerouted.
6822 |
6823 |
6824 | Parameters
6825 | -----
6826 | pNotification (in)
6827 |     A pointer to a structure containing information about the event. Use the `pDevice` member of
6828 |     this object to retrieve the relevant device. The `type` member can be used to discriminate
6829 |     against each of the notification types.
6830 |
6831 |
6832 | Remarks
6833 | -----
6834 | Do not restart or uninitialized the device from the callback.
6835 |
6836 | Not all notifications will be triggered by all backends, however the started and stopped events
6837 | should be reliable for all backends. Some backends do not have a good way to detect device
6838 | stoppages due to unplugging the device which may result in the stopped callback not getting
6839 | fired. This has been observed with at least one BSD variant.
6840 |
6841 | The rerouted notification is fired *after* the reroute has occurred. The stopped notification will
6842 | *not* get fired when a device is rerouted. The following backends are known to do automatic stream
6843 | rerouting, but do not have a way to be notified of the change:
6844 |
6845 |     * DirectSound
6846 |
6847 | The interruption notifications are used on mobile platforms for detecting when audio is interrupted
6848 | due to things like an incoming phone call. Currently this is only implemented on iOS. None of the
6849 | Android backends will report this notification.
6850 | */
6851 | typedef void (* ma_device_notification_proc)(const ma_device_notification* pNotification);
6852 |
6853 |
6854 | /*
6855 | The callback for processing audio data from the device.
6856 |
6857 | The data callback is fired by miniaudio whenever the device needs to have more data delivered to a
6858 | > playback device, or when a capture device has some data
6859 | > available. This is called as soon as the backend asks for more data which means it may be called
6860 | > with inconsistent frame counts. You cannot assume the
6861 | > callback will be fired with a consistent frame count.
6862 |
6863 | Parameters
6864 | -----
6865 | pDevice (in)
6866 |     A pointer to the relevant device.
6867 |
6868 | pOutput (out)
6869 |     A pointer to the output buffer that will receive audio data that will later be played back
6870 | > through the speakers. This will be non-null for a playback or
6871 | > full-duplex device and null for a capture and loopback device.
6872 |
6873 | pInput (in)
6874 |     A pointer to the buffer containing input data from a recording device. This will be non-null for
6875 | > a capture, full-duplex or loopback device and null for a
6876 | > playback device.
6877 |
6878 | frameCount (in)
6879 |     The number of PCM frames to process. Note that this will not necessarily be equal to what you
6880 | > requested when you initialized the device. The
6881 | > `periodSizeInFrames` and `periodSizeInMilliseconds` members of the device config are just hints,
6882 | > and are not necessarily exactly what you'll get. You must
6883 | > not assume this will always be the same value each time the callback is fired.
6884 |
6885 | Remarks
6886 | -----
6887 | You cannot stop and start the device from inside the callback or else you'll get a deadlock. You
6888 | > must also not uninitialized the device from inside the
6889 | > callback. The following APIs cannot be called from inside the callback:
6890 |
6891 |     ma_device_init()
6892 |     ma_device_init_ex()
6893 |     ma_device_uninit()
6894 |     ma_device_start()

```

```

6890 |     ma_device_stop()
6891 |
6892 | The proper way to stop the device is to call `ma_device_stop()` from a different thread, normally
> the main application thread.
6893 | */
6894 | typedef void (* ma_device_data_proc)(ma_device* pDevice, void* pOutput, const void* pInput,
> ma_uint32 frameCount);
6895 |
6896 |
6897 |
6898 |
6899 | /*
6900 | DEPRECATED. Use ma_device_notification_proc instead.
6901 |
6902 | The callback for when the device has been stopped.
6903 |
6904 | This will be called when the device is stopped explicitly with `ma_device_stop()` and also called
> implicitly when the device is stopped through external forces
6905 | such as being unplugged or an internal error occurring.
6906 |
6907 |
6908 | Parameters
6909 | -----
6910 | pDevice (in)
6911 |     A pointer to the device that has just stopped.
6912 |
6913 |
6914 | Remarks
6915 | -----
6916 | Do not restart or uninitialized the device from the callback.
6917 | */

7227 |
7228 | /*
7229 | These are the callbacks required to be implemented for a backend. These callbacks are grouped into
7230 | > two parts: context and device. There is one context
7231 | > to many devices. A device is created from a context.
7232 |
7233 | The general flow goes like this:
7234 |
7235 | 1) A context is created with `onContextInit()`
7236 | 1a) Available devices can be enumerated with `onContextEnumerateDevices()` if required.
7237 | 1b) Detailed information about a device can be queried with `onContextGetDeviceInfo()` if
7238 | > required.
7239 | 2) A device is created from the context that was created in the first step using `onDeviceInit()`,
7240 | > and optionally a device ID that was
7241 |     selected from device enumeration via `onContextEnumerateDevices()`.
7242 | 3) A device is started or stopped with `onDeviceStart()` / `onDeviceStop()`

```

```

7237 | 4) Data is delivered to and from the device by the backend. This is always done based on the
7238 | > native format returned by the prior call
7239 | to `onDeviceInit()`. Conversion between the device's native format and the format requested by
7240 | > the application will be handled by
7241 | miniaudio internally.
7242 | Initialization of the context is quite simple. You need to do any necessary initialization of
7243 | > internal objects and then output the
7244 | callbacks defined in this structure.
7245 | Once the context has been initialized you can initialize a device. Before doing so, however, the
7246 | > application may want to know which
7247 | physical devices are available. This is where `onContextEnumerateDevices()` comes in. This is fairly
7248 | > simple. For each device, fire the
7249 | given callback with, at a minimum, the basic information filled out in `ma_device_info`. When the
7250 | > callback returns `MA_FALSE`, enumeration
7251 | needs to stop and the `onContextEnumerateDevices()` function returns with a success code.
7252 | Detailed device information can be retrieved from a device ID using `onContextGetDeviceInfo()`. This
7253 | > takes as input the device type and ID,
7254 | and on output returns detailed information about the device in `ma_device_info`. The
7255 | > `onContextGetDeviceInfo()` callback must handle the
7256 | case when the device ID is NULL, in which case information about the default device needs to be
7257 | > retrieved.
7258 | Once the context has been created and the device ID retrieved (if using anything other than the
7259 | > default device), the device can be created.
7260 | This is a little bit more complicated than initialization of the context due to its more complicated
7261 | > configuration. When initializing a
7262 | device, a duplex device may be requested. This means a separate data format needs to be specified
7263 | > for both playback and capture. On input,
7264 | the data format is set to what the application wants. On output it's set to the native format which
7265 | > should match as closely as possible to
7266 | the requested format. The conversion between the format requested by the application and the
7267 | > device's native format will be handled
7268 | internally by miniaudio.
7269 | On input, if the sample format is set to `ma_format_unknown`, the backend is free to use whatever
7270 | > sample format it desires, so long as it's
7271 | supported by miniaudio. When the channel count is set to 0, the backend should use the device's
7272 | > native channel count. The same applies for
7273 | sample rate. For the channel map, the default should be used when `ma_channel_map_is_blank()`
7274 | > returns true (all channels set to
7275 | `MA_CHANNEL_NONE`). On input, the `periodSizeInFrames` or `periodSizeInMilliseconds` option should
7276 | > always be set. The backend should
7277 | inspect both of these variables. If `periodSizeInFrames` is set, it should take priority, otherwise
7278 | > it needs to be derived from the period
7279 | size in milliseconds (`periodSizeInMilliseconds`) and the sample rate, keeping in mind that the
7280 | > sample rate may be 0, in which case the
7281 | sample rate will need to be determined before calculating the period size in frames. On output, all
7282 | > members of the `ma_device_descriptor`
7283 | object should be set to a valid value, except for `periodSizeInMilliseconds` which is optional
7284 | > (`periodSizeInFrames` *must* be set).
7285 | Starting and stopping of the device is done with `onDeviceStart()` and `onDeviceStop()` and should
7286 | > be self-explanatory. If the backend uses
7287 | asynchronous reading and writing, `onDeviceStart()` and `onDeviceStop()` should always be
7288 | > implemented.
7289 | The handling of data delivery between the application and the device is the most complicated part of
7290 | > the process. To make this a bit
7291 | easier, some helper callbacks are available. If the backend uses a blocking read/write style of API,
7292 | > the `onDeviceRead()` and
7293 | `onDeviceWrite()` callbacks can optionally be implemented. These are blocking and work just like
7294 | > reading and writing from a file. If the
7295 | backend uses a callback for data delivery, that callback must call
7296 | > `ma_device_handle_backend_data_callback()` from within its callback.
7297 | This allows miniaudio to then process any necessary data conversion and then pass it to the
7298 | > miniaudio data callback.
7299 | If the backend requires absolute flexibility with its data delivery, it can optionally implement the
7300 | > `onDeviceDataLoop()` callback
7301 | which will allow it to implement the logic that will run on the audio thread. This is much more
7302 | > advanced and is completely optional.
7303 | The audio thread should run data delivery logic in a loop while `ma_device_get_state() ==
7304 | > ma_device_state_started` and no errors have been
7305 | encountered. Do not start or stop the device here. That will be handled from outside the
7306 | > `onDeviceDataLoop()` callback.

```

```

7283 |
7284 | The invocation of the `onDeviceDataLoop()` callback will be handled by miniaudio. When you start the
> device, miniaudio will fire this
7285 | callback. When the device is stopped, the `ma_device_get_state() == ma_device_state_started`
> condition will fail and the loop will be terminated
7286 | which will then fall through to the part that stops the device. For an example on how to implement
> the `onDeviceDataLoop()` callback,
7287 | look at `ma_device_audio_thread_default_read_write()`. Implement the `onDeviceDataLoopWakeup()`
> callback if you need a mechanism to
7288 | wake up the audio thread.
7289 |
7290 | If the backend supports an optimized retrieval of device information from an initialized `ma_device`
> object, it should implement the
7291 | `onDeviceGetInfo()` callback. This is optional, in which case it will fall back to
> `onContextGetDeviceInfo()` which is less efficient.

```

8084 | /*
8085 | Initializes a `ma_context_config` object.
8086 |
8087 |
8088 | Return Value
8089 | -----
8090 | A `ma_context_config` initialized to defaults.
8091 |
8092 |
8093 | Remarks
8094 | -----
8095 | You must always use this to initialize the default state of the `ma_context_config` object. Not
> using this will result in your program breaking when miniaudio
8096 | is updated and new members are added to `ma_context_config`. It also sets logical defaults.
8097 |
8098 | You can override members of the returned object by changing it's members directly.
8099 |
8100 |
8101 | See Also
8102 | -----
8103 | ma_context_init()
8104 | */
8105 | MA_API ma_context_config ma_context_config_init(void);
8106 |
8107 | /*
8108 | Initializes a context.
8109 |
8110 | The context is used for selecting and initializing an appropriate backend and to represent the
> backend at a more global level than that of an individual
8111 | device. There is one context to many devices, and a device is created from a context. A context is
> required to enumerate devices.
8112 |
8113 |
8114 | Parameters
8115 | -----
8116 | backends (in, optional)
8117 |     A list of backends to try initializing, in priority order. Can be NULL, in which case it uses
> default priority order.
8118 |
8119 | backendCount (in, optional)
8120 |     The number of items in `backend`. Ignored if `backend` is NULL.
8121 |
8122 | pConfig (in, optional)
8123 |     The context configuration.
8124 |
8125 | pContext (in)
8126 |     A pointer to the context object being initialized.
8127 |
8128 |
8129 | Return Value
8130 | -----
8131 | MA_SUCCESS if successful; any other error code otherwise.
8132 |
8133 |
8134 | Thread Safety
8135 | -----
8136 | Unsafe. Do not call this function across multiple threads as some backends read and write to global
> state.
8137 |
8138 |
8139 | Remarks
8140 | -----
8141 | When `backends` is NULL, the default priority order will be used. Below is a list of backends in
> priority order:
8142 |
8143 | |-----|-----|-----|
8144 | | Name | Enum Name | Supported Operating Systems |
8145 | |-----|-----|-----|
8146 | | WASAPI | ma_backend_wasapi | Windows Vista+ |
8147 | | DirectSound | ma_backend_dsound | Windows XP+ |
8148 | | WinMM | ma_backend_winmm | Windows XP+ (may work on older versions, but untested) |
8149 | | Core Audio | ma_backend_coreaudio | macOS, iOS |
8150 | | ALSA | ma_backend_alsa | Linux |
8151 | | PulseAudio | ma_backend_pulseaudio | Cross Platform (disabled on Windows, BSD and Android) |
8152 | | JACK | ma_backend_jack | Cross Platform (disabled on BSD and Android) |
8153 | | sndio | ma_backend_sndio | OpenBSD |
8154 | | audio(4) | ma_backend_audio4 | NetBSD, OpenBSD |
8155 | | OSS | ma_backend_oss | FreeBSD |
8156 | | AAudio | ma_backend_aaudio | Android 8+ |

```

```

8157 | | OpenSLES | ma_backend_opensl | Android (API level 16+) |
8158 | | Web Audio | ma_backend_webaudio | Web (via Emscripten) |
8159 | | Null | ma_backend_null | Cross Platform (not used on Web) |
8160 | |-----|-----|-----|
8161 |
8162 | The context can be configured via the `pConfig` argument. The config object is initialized with
> `ma_context_config_init()`. Individual configuration settings
8163 | can then be set directly on the structure. Below are the members of the `ma_context_config` object.
8164 |
8165 | pLog
8166 |     A pointer to the `ma_log` to post log messages to. Can be NULL if the application does not
8167 |     require logging. See the `ma_log` API for details on how to use the logging system.
8168 |
8169 | threadPriority
8170 |     The desired priority to use for the audio thread. Allowable values include the following:
8171 |
8172 |     |-----|
8173 |     | Thread Priority |
8174 |     |-----|
8175 |     | ma_thread_priority_idle |
8176 |     | ma_thread_priority_lowest |
8177 |     | ma_thread_priority_low |
8178 |     | ma_thread_priority_normal |
8179 |     | ma_thread_priority_high |
8180 |     | ma_thread_priority_highest (default) |
8181 |     | ma_thread_priority_realtime |
8182 |     | ma_thread_priority_default |
8183 |     |-----|
8184 |
8185 | threadStackSize
8186 |     The desired size of the stack for the audio thread. Defaults to the operating system's
> default.
8187 |
8188 | pUserData
8189 |     A pointer to application-defined data. This can be accessed from the context object directly
> such as `context.pUserData`.
8190 |
8191 | allocationCallbacks
8192 |     Structure containing custom allocation callbacks. Leaving this at defaults will cause it to
> use MA_MALLOC, MA_REALLOC and MA_FREE. These allocation
8193 | callbacks will be used for anything tied to the context, including devices.
8194 |
8195 | alsa.useVerboseDeviceEnumeration
8196 |     ALSA will typically enumerate many different devices which can be intrusive and not
> user-friendly. To combat this, miniaudio will enumerate only unique
8197 | card/device pairs by default. The problem with this is that you lose a bit of flexibility
> and control. Setting alsa.useVerboseDeviceEnumeration makes
8198 | it so the ALSA backend includes all devices. Defaults to false.
8199 |
8200 | pulse.pApplicationName
8201 |     PulseAudio only. The application name to use when initializing the PulseAudio context with
> `pa_context_new()`.
8202 |
8203 | pulse.pServerName
8204 |     PulseAudio only. The name of the server to connect to with `pa_context_connect()`.
8205 |
8206 | pulse.tryAutoSpawn
8207 |     PulseAudio only. Whether or not to try automatically starting the PulseAudio daemon.
> Defaults to false. If you set this to true, keep in mind that
8208 | miniaudio uses a trial and error method to find the most appropriate backend, and this will
> result in the PulseAudio daemon starting which may be
8209 | intrusive for the end user.
8210 |
8211 | coreaudio.sessionCategory
8212 |     iOS only. The session category to use for the shared AudioSession instance. Below is a list
> of allowable values and their Core Audio equivalents.
8213 |
8214 |     |-----|-----|
8215 |     | miniaudio Token | Core Audio Token |
8216 |     |-----|-----|
8217 |     | ma_ios_session_category_ambient | AVAudioSessionCategoryAmbient |
8218 |     | ma_ios_session_category_solo_ambient | AVAudioSessionCategorySoloAmbient |
8219 |     | ma_ios_session_category_playback | AVAudioSessionCategoryPlayback |
8220 |     | ma_ios_session_category_record | AVAudioSessionCategoryRecord |
8221 |     | ma_ios_session_category_play_and_record | AVAudioSessionCategoryPlayAndRecord |
8222 |     | ma_ios_session_category_multi_route | AVAudioSessionCategoryMultiRoute |
8223 |     | ma_ios_session_category_none | AVAudioSessionCategoryAmbient |
8224 |     | ma_ios_session_category_default | AVAudioSessionCategoryAmbient |
8225 |     |-----|-----|

```

```

8226 |
8227 |     coreaudio.sessionCategoryOptions
8228 |         iOS only. Session category options to use with the shared AudioSession instance. Below is a
> list of allowable values and their Core Audio equivalents.
8229 |
8230 | |-----|-----|-----|
8231 | | miniaudio Token | | Core Audio
> Token |
8232 | |-----|-----|-----|
8233 | | ma_ios_session_category_option_mix_with_others | |
> AVAudioSessionCategoryOptionMixWithOthers |
8234 | | ma_ios_session_category_option_duck_others | |
> AVAudioSessionCategoryOptionDuckOthers |
8235 | | ma_ios_session_category_option_allow_bluetooth | |
> AVAudioSessionCategoryOptionAllowBluetooth |
8236 | | ma_ios_session_category_option_default_to_speaker | |
> AVAudioSessionCategoryOptionDefaultToSpeaker |
8237 | | ma_ios_session_category_option_interrupt_spoken_audio_and_mix_with_others | |
> AVAudioSessionCategoryOptionInterruptSpokenAudioAndMixWithOthers |
8238 | | ma_ios_session_category_option_allow_bluetooth_a2dp | |
> AVAudioSessionCategoryOptionAllowBluetoothA2DP |
8239 | | ma_ios_session_category_option_allow_air_play | |
> AVAudioSessionCategoryOptionAllowAirPlay |
8240 | |-----|-----|-----|
8241 |
8242 |     coreaudio.noAudioSessionActivate
8243 |         iOS only. When set to true, does not perform an explicit [[AVAudioSession sharedInstance]
> setActive:true] on initialization.
8244 |
8245 |     coreaudio.noAudioSessionDeactivate
8246 |         iOS only. When set to true, does not perform an explicit [[AVAudioSession sharedInstance]
> setActive:false] on uninitialization.
8247 |
8248 |     jack.pClientName
8249 |         The name of the client to pass to `jack_client_open()`.
8250 |
8251 |     jack.tryStartServer
8252 |         Whether or not to try auto-starting the JACK server. Defaults to false.
8253 |
8254 |
8255 | It is recommended that only a single context is active at any given time because it's a bulky data
> structure which performs run-time linking for the
8256 | relevant backends every time it's initialized.
8257 |
8258 | The location of the context cannot change throughout it's lifetime. Consider allocating the
> `ma_context` object with `malloc()` if this is an issue. The
8259 | reason for this is that a pointer to the context is stored in the `ma_device` structure.
8260 |
8261 |
8262 | Example 1 - Default Initialization
8263 | -----
8264 | The example below shows how to initialize the context using the default configuration.
8265 |
8266 | ```c
8267 | ma_context context;
8268 | ma_result result = ma_context_init(NULL, 0, NULL, &context);
8269 | if (result != MA_SUCCESS) {
8270 |     // Error.
8271 | }
8272 | ```
8273 |
8274 |
8275 | Example 2 - Custom Configuration
8276 | -----
8277 | The example below shows how to initialize the context using custom backend priorities and a custom
> configuration. In this hypothetical example, the program
8278 | wants to prioritize ALSA over PulseAudio on Linux. They also want to avoid using the WinMM backend
> on Windows because it's latency is too high. They also
8279 | want an error to be returned if no valid backend is available which they achieve by excluding the
> Null backend.
8280 |
8281 | For the configuration, the program wants to capture any log messages so they can, for example, route
> it to a log file and user interface.
8282 |
8283 | ```c
8284 | ma_backend backends[] = {

```

```

8285 |     ma_backend_alsa,
8286 |     ma_backend_pulseaudio,
8287 |     ma_backend_wasapi,
8288 |     ma_backend_dsound
8289 | };
8290 |
8291 | ma_log log;
8292 | ma_log_init(&log);
8293 | ma_log_register_callback(&log, ma_log_callback_init(my_log_callback, pMyLogUserData));
8294 |
8295 | ma_context_config config = ma_context_config_init();
8296 | config.pLog = &log; // Specify a custom log object in the config so any logs that are posted from
> ma_context_init() are captured.
8297 |
8298 | ma_context context;
8299 | ma_result result = ma_context_init(backends, sizeof(backends)/sizeof(backends[0]), &config,
> &context);
8300 | if (result != MA_SUCCESS) {
8301 |     // Error.
8302 |     if (result == MA_NO_BACKEND) {
8303 |         // Couldn't find an appropriate backend.
8304 |     }
8305 | }
8306 |
8307 | // You could also attach a log callback post-initialization:
8308 | ma_log_register_callback(ma_context_get_log(&context), ma_log_callback_init(my_log_callback,
> pMyLogUserData));
8309 | ```
8310 |
8311 |
8312 | See Also
8313 | -----
8314 | ma_context_config_init()
8315 | ma_context_uninit()
8316 | */
8317 | MA_API ma_result ma_context_init(const ma_backend backends[], ma_uint32 backendCount, const
> ma_context_config* pConfig, ma_context* pContext);
8318 |
8319 | /*
8320 | Uninitializes a context.
8321 |
8322 |
8323 | Return Value
8324 | -----
8325 | MA_SUCCESS if successful; any other error code otherwise.
8326 |
8327 |
8328 | Thread Safety
8329 | -----
8330 | Unsafe. Do not call this function across multiple threads as some backends read and write to global
> state.
8331 |
8332 |
8333 | Remarks
8334 | -----
8335 | Results are undefined if you call this while any device created by this context is still active.
8336 |
8337 |
8338 | See Also
8339 | -----
8340 | ma_context_init()
8341 | */
8342 | MA_API ma_result ma_context_uninit(ma_context* pContext);
8343 |
8344 | /*
8345 | Retrieves the size of the ma_context object.
8346 |
8347 | This is mainly for the purpose of bindings to know how much memory to allocate.
8348 | */
8349 | MA_API size_t ma_context_sizeof(void);
8350 |
8351 | /*
8352 | Retrieves a pointer to the log object associated with this context.
8353 |
8354 |
8355 | Remarks
8356 | -----
8357 | Pass the returned pointer to `ma_log_post()`, `ma_log_postv()` or `ma_log_postf()` to post a log
8358 | message.

```

```

8359 |
8360 | You can attach your own logging callback to the log with `ma_log_register_callback()`
8361 |
8362 |
8363 | Return Value
8364 | -----
8365 | A pointer to the `ma_log` object that the context uses to post log messages. If some error occurs,
8366 | NULL will be returned.
8367 | */
8368 | MA_API ma_log* ma_context_get_log(ma_context* pContext);
8369 |
8370 | /*
8371 | Enumerates over every device (both playback and capture).
8372 |
8373 | This is a lower-level enumeration function to the easier to use `ma_context_get_devices()`. Use
8374 | > `ma_context_enumerate_devices()` if you would rather not incur
8375 | an internal heap allocation, or it simply suits your code better.
8376 | Note that this only retrieves the ID and name/description of the device. The reason for only
8377 | > retrieving basic information is that it would otherwise require
8378 | opening the backend device in order to probe it for more detailed information which can be
8379 | > inefficient. Consider using `ma_context_get_device_info()` for this,
8380 | but don't call it from within the enumeration callback.
8381 |
8382 | Returning false from the callback will stop enumeration. Returning true will continue enumeration.
8383 |
8384 | Parameters
8385 | -----
8386 | pContext (in)
8387 |     A pointer to the context performing the enumeration.
8388 | callback (in)
8389 |     The callback to fire for each enumerated device.
8390 |
8391 | pUserData (in)
8392 |     A pointer to application-defined data passed to the callback.
8393 |
8394 | Return Value
8395 | -----
8396 | MA_SUCCESS if successful; any other error code otherwise.
8397 |
8398 | Thread Safety
8399 | -----
8400 | Safe. This is guarded using a simple mutex lock.
8401 |
8402 | Remarks
8403 | -----
8404 | Do _not_ assume the first enumerated device of a given type is the default device.
8405 | Some backends and platforms may only support default playback and capture devices.
8406 |
8407 | In general, you should not do anything complicated from within the callback. In particular, do not
8408 | > try initializing a device from within the callback. Also,
8409 | do not try to call `ma_context_get_device_info()` from within the callback.
8410 | Consider using `ma_context_get_devices()` for a simpler and safer API, albeit at the expense of an
8411 | > internal heap allocation.
8412 |
8413 | Example 1 - Simple Enumeration
8414 | -----
8415 | ma_bool32 ma_device_enum_callback(ma_context* pContext, ma_device_type deviceType, const
8416 | > ma_device_info* pInfo, void* pUserData)
8417 | {
8418 |     printf("Device Name: %s\n", pInfo->name);
8419 |     return MA_TRUE;
8420 | }
8421 |
8422 | ma_result result = ma_context_enumerate_devices(&context, my_device_enum_callback, pMyUserData);
8423 | if (result != MA_SUCCESS) {
8424 |     // Error.
8425 | }
8426 |
8427 | See Also

```

```

8432 | -----
8433 | ma_context_get_devices()
8434 | */
8435 | MA_API ma_result ma_context_enumerate_devices(ma_context* pContext, ma_enum_devices_callback_proc
> callback, void* pUserData);
8436 |
8437 | /*
8438 | Retrieves basic information about every active playback and/or capture device.
8439 |
8440 | This function will allocate memory internally for the device lists and return a pointer to them
> through the `ppPlaybackDeviceInfos` and `ppCaptureDeviceInfos`
8441 | parameters. If you do not want to incur the overhead of these allocations consider using
> `ma_context_enumerate_devices()` which will instead use a callback.
8442 |
8443 | Note that this only retrieves the ID and name/description of the device. The reason for only
> retrieving basic information is that it would otherwise require
8444 | opening the backend device in order to probe it for more detailed information which can be
> inefficient. Consider using `ma_context_get_device_info()` for this,
8445 | but don't call it from within the enumeration callback.
8446 |
8447 |
8448 | Parameters
8449 | -----
8450 | pContext (in)
8451 |     A pointer to the context performing the enumeration.
8452 |
8453 | ppPlaybackDeviceInfos (out)
8454 |     A pointer to a pointer that will receive the address of a buffer containing the list of
> `ma_device_info` structures for playback devices.
8455 |
8456 | pPlaybackDeviceCount (out)
8457 |     A pointer to an unsigned integer that will receive the number of playback devices.
8458 |
8459 | ppCaptureDeviceInfos (out)
8460 |     A pointer to a pointer that will receive the address of a buffer containing the list of
> `ma_device_info` structures for capture devices.
8461 |
8462 | pCaptureDeviceCount (out)
8463 |     A pointer to an unsigned integer that will receive the number of capture devices.

8468 | MA_SUCCESS if successful; any other error code otherwise.
8469 |
8470 |
8471 | Thread Safety
8472 | -----
8473 | Unsafe. Since each call to this function invalidates the pointers from the previous call, you should
> not be calling this simultaneously across multiple
8474 | threads. Instead, you need to make a copy of the returned data with your own higher level
> synchronization.
8475 |
8476 |
8477 | Remarks
8478 | -----
8479 | It is not safe to assume the first device in the list is the default device.
8480 |
8481 | You can pass in NULL for the playback or capture lists in which case they'll be ignored.
8482 |
8483 | The returned pointers will become invalid upon the next call this this function, or when the context
> is uninitialized. Do not free the returned pointers.
8484 |
8485 |
8486 | See Also
8487 | -----
8488 | ma_context_enumerate_devices()
8489 | */
8490 | MA_API ma_result ma_context_get_devices(ma_context* pContext, ma_device_info**
> ppPlaybackDeviceInfos, ma_uint32* pPlaybackDeviceCount, ma_device_info** ppCaptureDeviceInfos,
> ma_uint32* pCaptureDeviceCount);
8491 |
8492 | /*
8493 | Retrieves information about a device of the given type, with the specified ID and share mode.
8494 |
8495 |
8496 | Parameters
8497 | -----
8498 | pContext (in)

```

```

8499 |     A pointer to the context performing the query.
8500 |
8501 | deviceType (in)
8502 |     The type of the device being queried. Must be either `ma_device_type_playback` or
> `ma_device_type_capture`.
8503 |
8504 | pDeviceID (in)
8505 |     The ID of the device being queried.
8506 |
8507 | pDeviceInfo (out)
8508 |     A pointer to the `ma_device_info` structure that will receive the device information.
8509 |
8510 |
8511 | Return Value
8512 | -----
8513 | MA_SUCCESS if successful; any other error code otherwise.
8514 |
8515 |
8516 | Thread Safety
8517 | -----
8518 | Safe. This is guarded using a simple mutex lock.
8519 |
8520 |
8521 | Remarks
8522 | -----
8523 | Do not call this from within the `ma_context_enumerate_devices()` callback.
8524 |
8525 | It's possible for a device to have different information and capabilities depending on whether or
> not it's opened in shared or exclusive mode. For example, in
8526 | shared mode, WASAPI always uses floating point samples for mixing, but in exclusive mode it can be
> anything. Therefore, this function allows you to specify
8527 | which share mode you want information for. Note that not all backends and devices support shared or
> exclusive mode, in which case this function will fail if
8528 | the requested share mode is unsupported.
8529 |
8530 | This leaves pDeviceInfo unmodified in the result of an error.
8531 | */
8532 | MA_API ma_result ma_context_get_device_info(ma_context* pContext, ma_device_type deviceType, const
> ma_device_id* pDeviceID, ma_device_info* pDeviceInfo);
8533 |
8534 | /*
8535 | Determines if the given context supports loopback mode.
8536 |
8537 |
8538 | Parameters
8539 | -----
8540 | pContext (in)
8541 |     A pointer to the context getting queried.
8542 |
8543 |
8544 | Return Value
8545 | -----
8546 | MA_TRUE if the context supports loopback mode; MA_FALSE otherwise.
8547 | */
8548 | MA_API ma_bool32 ma_context_is_loopback_supported(ma_context* pContext);
8549 |
8550 |
8551 |
8552 | /*
8553 | Initializes a device config with default settings.
8554 |
8555 |
8556 | Parameters
8557 | -----
8558 | deviceType (in)
8559 |     The type of the device this config is being initialized for. This must set to one of the
> following:
8560 |
8561 | |-----|
8562 | | Device Type |
8563 | |-----|
8564 | | ma_device_type_playback |
8565 | | ma_device_type_capture |
8566 | | ma_device_type_duplex |
8567 | | ma_device_type_loopback |
8568 | |-----|
8569 |
8570 |
8571 | Return Value

```

```

8572 | -----
8573 | A new device config object with default settings. You will typically want to adjust the config after
> this function returns. See remarks.
8574 |
8575 |
8576 | Thread Safety
8577 | -----
8578 | Safe.
8579 |
8580 |
8581 | Callback Safety
8582 | -----
8583 | Safe, but don't try initializing a device in a callback.
8584 |
8585 |
8586 | Remarks
8587 | -----
8588 | The returned config will be initialized to defaults. You will normally want to customize a few
> variables before initializing the device. See Example 1 for a
8589 | typical configuration which sets the sample format, channel count, sample rate, data callback and
> user data. These are usually things you will want to change
8590 | before initializing the device.
8591 |
8592 | See `ma_device_init()` for details on specific configuration options.
8593 |
8594 |
8595 | Example 1 - Simple Configuration
8596 | -----
8597 | The example below is what a program will typically want to configure for each device at a minimum.
> Notice how `ma_device_config_init()` is called first, and
8598 | then the returned object is modified directly. This is important because it ensures that your
> program continues to work as new configuration options are added
8599 | to the `ma_device_config` structure.
8600 |
8601 | ```c
8602 | ma_device_config config = ma_device_config_init(ma_device_type_playback);
8603 | config.playback.format = ma_format_f32;
8604 | config.playback.channels = 2;
8605 | config.sampleRate = 48000;
8606 | config.dataCallback = ma_data_callback;
8607 | config.pUserData = pMyUserData;
8608 | ```
8609 |
8610 |
8611 | See Also
8612 | -----
8613 | ma_device_init()
8614 | ma_device_init_ex()
8615 | */
8616 | MA_API ma_device_config ma_device_config_init(ma_device_type deviceType);
8617 |
8618 |
8619 | /*
8620 | Initializes a device.
8621 |
8622 | A device represents a physical audio device. The idea is you send or receive audio data from the
> device to either play it back through a speaker, or capture it
8623 | from a microphone. Whether or not you should send or receive data from the device (or both) depends
> on the type of device you are initializing which can be
8624 | playback, capture, full-duplex or loopback. (Note that loopback mode is only supported on select
> backends.) Sending and receiving audio data to and from the
8625 | device is done via a callback which is fired by miniaudio at periodic time intervals.
8626 |
8627 | The frequency at which data is delivered to and from a device depends on the size of its period. The
> size of the period can be defined in terms of PCM frames
8628 | or milliseconds, whichever is more convenient. Generally speaking, the smaller the period, the lower
> the latency at the expense of higher CPU usage and
8629 | increased risk of glitching due to the more frequent and granular data deliver intervals. The size
> of a period will depend on your requirements, but
8630 | miniaudio's defaults should work fine for most scenarios. If you're building a game you should leave
> this fairly small, whereas if you're building a simple
8631 | media player you can make it larger. Note that the period size you request is actually just a hint -
> miniaudio will tell the backend what you want, but the
8632 | backend is ultimately responsible for what it gives you. You cannot assume you will get exactly what
> you ask for.
8633 |
8634 | When delivering data to and from a device you need to make sure it's in the correct format which you
> can set through the device configuration. You just set the
8635 | format that you want to use and miniaudio will perform all of the necessary conversion for you

```

```

> internally. When delivering data to and from the callback you
8636 | can assume the format is the same as what you requested when you initialized the device. See Remarks
> | for more details on miniaudio's data conversion pipeline.
8637 |
8638 |
8639 | Parameters
8640 | -----
8641 | pContext (in, optional)
8642 |     A pointer to the context that owns the device. This can be null, in which case it creates a
> | default context internally.
8643 |
8644 | pConfig (in)
8645 |     A pointer to the device configuration. Cannot be null. See remarks for details.
8646 |
8647 | pDevice (out)
8648 |     A pointer to the device object being initialized.
8649 |
8650 |
8651 | Return Value
8652 | -----
8653 | MA_SUCCESS if successful; any other error code otherwise.
8654 |
8655 |
8656 | Thread Safety
8657 | -----
8658 | Unsafe. It is not safe to call this function simultaneously for different devices because some
> | backends depend on and mutate global state. The same applies to
8659 | calling this at the same time as `ma_device_uninit()`.
8660 |
8661 |
8662 | Callback Safety
8663 | -----
8664 | Unsafe. It is not safe to call this inside any callback.
8665 |
8666 |
8667 | Remarks
8668 | -----
8669 | Setting `pContext` to NULL will result in miniaudio creating a default context internally and is
> | equivalent to passing in a context initialized like so:
8670 |
8671 |     ```c
8672 |     ma_context_init(NULL, 0, NULL, &context);
8673 |     ```
8674 |
8675 | Do not set `pContext` to NULL if you are needing to open multiple devices. You can, however, use
> | NULL when initializing the first device, and then use
8676 | device.pContext for the initialization of other devices.
8677 |
8678 | The device can be configured via the `pConfig` argument. The config object is initialized with
> | `ma_device_config_init()`. Individual configuration settings can
8679 | then be set directly on the structure. Below are the members of the `ma_device_config` object.
8680 |
8681 |     deviceType
8682 |         Must be `ma_device_type_playback`, `ma_device_type_capture`, `ma_device_type_duplex` of
> | `ma_device_type_loopback`.
8683 |
8684 |     sampleRate
8685 |         The sample rate, in hertz. The most common sample rates are 48000 and 44100. Setting this to
> | 0 will use the device's native sample rate.
8686 |
8687 |     periodSizeInFrames
8688 |         The desired size of a period in PCM frames. If this is 0, `periodSizeInMilliseconds` will be
> | used instead. If both are 0 the default buffer size will
8689 | be used depending on the selected performance profile. This value affects latency. See below
> | for details.
8690 |
8691 |     periodSizeInMilliseconds
8692 |         The desired size of a period in milliseconds. If this is 0, `periodSizeInFrames` will be
> | used instead. If both are 0 the default buffer size will be
8693 | used depending on the selected performance profile. The value affects latency. See below for
> | details.
8694 |
8695 |     periods
8696 |         The number of periods making up the device's entire buffer. The total buffer size is
> | `periodSizeInFrames` or `periodSizeInMilliseconds` multiplied by
8697 | this value. This is just a hint as backends will be the ones who ultimately decide how your
> | periods will be configured.
8698 |
8699 |     performanceProfile

```

```

8700 |         A hint to miniaudio as to the performance requirements of your program. Can be either
8701 | > `ma_performance_profile_low_latency` (default) or
8702 | > `ma_performance_profile_conservative`. This mainly affects the size of default buffers and
8703 | > can usually be left at its default value.
8704 |
8705 |     noPreSilencedOutputBuffer
8706 |         When set to true, the contents of the output buffer passed into the data callback will be
8707 | > left undefined. When set to false (default), the contents of
8708 | > the output buffer will be cleared the zero. You can use this to avoid the overhead of
8709 | > zeroing out the buffer if you can guarantee that your data
8710 | > callback will write to every sample in the output buffer, or if you are doing your own
8711 | > clearing.
8712 |
8713 |     noClip
8714 |         When set to true, the contents of the output buffer are left alone after returning and it
8715 | > will be left up to the backend itself to decide whether or
8716 | > not to clip. When set to false (default), the contents of the output buffer passed into the
8717 | > data callback will be clipped after returning. This only
8718 | > applies when the playback sample format is f32.
8719 |
8720 |     noDisableDenormals
8721 |         By default, miniaudio will disable denormals when the data callback is called. Setting this
8722 | > to true will prevent the disabling of denormals.
8723 |
8724 |     noFixedSizedCallback
8725 |         Allows miniaudio to fire the data callback with any frame count. When this is set to false
8726 | > (the default), the data callback will be fired with a
8727 | > consistent frame count as specified by `periodSizeInFrames` or `periodSizeInMilliseconds`.
8728 | > When set to true, miniaudio will fire the callback with
8729 | > whatever the backend requests, which could be anything.
8730 |
8731 |     dataCallback
8732 |         The callback to fire whenever data is ready to be delivered to or from the device.
8733 |
8734 |     notificationCallback
8735 |         The callback to fire when something has changed with the device, such as whether or not it
8736 | > has been started or stopped.
8737 |
8738 |     pUserData
8739 |         The user data pointer to use with the device. You can access this directly from the device
8740 | > object like `device.pUserData`.
8741 |
8742 |     resampling.algorithm
8743 |         The resampling algorithm to use when miniaudio needs to perform resampling between the rate
8744 | > specified by `sampleRate` and the device's native rate. The
8745 | > default value is `ma_resample_algorithm_linear`, and the quality can be configured with
8746 | > `resampling.linear.lpfOrder`.
8747 |
8748 |     resampling.pBackendVTable
8749 |         A pointer to an optional vtable that can be used for plugging in a custom resampler.
8750 |
8751 |     resampling.pBackendUserData
8752 |         A pointer that will passed to callbacks in pBackendVTable.
8753 |
8754 |     resampling.linear.lpfOrder
8755 |         The linear resampler applies a low-pass filter as part of its processing for anti-aliasing.
8756 | > This setting controls the order of the filter. The higher
8757 | > the value, the better the quality, in general. Setting this to 0 will disable low-pass
8758 | > filtering altogether. The maximum value is
8759 | > `MA_MAX_FILTER_ORDER`. The default value is `min(4, MA_MAX_FILTER_ORDER)`.
8760 |
8761 |     playback.pDeviceID
8762 |         A pointer to a `ma_device_id` structure containing the ID of the playback device to
8763 | > initialize. Setting this NULL (default) will use the system's
8764 | > default playback device. Retrieve the device ID from the `ma_device_info` structure, which
8765 | > can be retrieved using device enumeration.
8766 |
8767 |     playback.format
8768 |         The sample format to use for playback. When set to `ma_format_unknown` the device's native
8769 | > format will be used. This can be retrieved after
8770 | > initialization from the device object directly with `device.playback.format`.
8771 |
8772 |     playback.channels
8773 |         The number of channels to use for playback. When set to 0 the device's native channel count
8774 | > will be used. This can be retrieved after initialization
8775 | > from the device object directly with `device.playback.channels`.
8776 |
8777 |     playback.pChannelMap
8778 |         The channel map to use for playback. When left empty, the device's native channel map will

```

```

> be used. This can be retrieved after initialization from the
8759 |     device object direct with `device.playback.pChannelMap`. When set, the buffer should contain
> `channels` items.
8760 |
8761 |     playback.shareMode
8762 |     The preferred share mode to use for playback. Can be either `ma_share_mode_shared` (default)
> or `ma_share_mode_exclusive`. Note that if you specify
8763 |     exclusive mode, but it's not supported by the backend, initialization will fail. You can
> then fall back to shared mode if desired by changing this to
8764 |     ma_share_mode_shared and reinitializing.
8765 |
8766 |     capture.pDeviceID
8767 |     A pointer to a `ma_device_id` structure containing the ID of the capture device to
> initialize. Setting this NULL (default) will use the system's
8768 |     default capture device. Retrieve the device ID from the `ma_device_info` structure, which
> can be retrieved using device enumeration.
8769 |
8770 |     capture.format
8771 |     The sample format to use for capture. When set to `ma_format_unknown` the device's native
> format will be used. This can be retrieved after
8772 |     initialization from the device object directly with `device.capture.format`.
8773 |
8774 |     capture.channels
8775 |     The number of channels to use for capture. When set to 0 the device's native channel count
> will be used. This can be retrieved after initialization
8776 |     from the device object directly with `device.capture.channels`.
8777 |
8778 |     capture.pChannelMap
8779 |     The channel map to use for capture. When left empty, the device's native channel map will be
> used. This can be retrieved after initialization from the
8780 |     device object direct with `device.capture.pChannelMap`. When set, the buffer should contain
> `channels` items.
8781 |
8782 |     capture.shareMode
8783 |     The preferred share mode to use for capture. Can be either `ma_share_mode_shared` (default)
> or `ma_share_mode_exclusive`. Note that if you specify
8784 |     exclusive mode, but it's not supported by the backend, initialization will fail. You can
> then fall back to shared mode if desired by changing this to
8785 |     ma_share_mode_shared and reinitializing.
8786 |
8787 |     wasapi.noAutoConvertSRC
8788 |     WASAPI only. When set to true, disables WASAPI's automatic resampling and forces the use of
> miniaudio's resampler. Defaults to false.
8789 |
8790 |     wasapi.noDefaultQualitySRC
8791 |     WASAPI only. Only used when `wasapi.noAutoConvertSRC` is set to false. When set to true,
> disables the use of `AUDCLNT_STREAMFLAGS_SRC_DEFAULT_QUALITY`.
8792 |     You should usually leave this set to false, which is the default.
8793 |
8794 |     wasapi.noAutoStreamRouting
8795 |     WASAPI only. When set to true, disables automatic stream routing on the WASAPI backend.
> Defaults to false.
8796 |
8797 |     wasapi.noHardwareOffloading
8798 |     WASAPI only. When set to true, disables the use of WASAPI's hardware offloading feature.
> Defaults to false.
8799 |
8800 |     alsa.noMMap
8801 |     ALSA only. When set to true, disables MMap mode. Defaults to false.
8802 |
8803 |     alsa.noAutoFormat
8804 |     ALSA only. When set to true, disables ALSA's automatic format conversion by including the
> SND_PCM_NO_AUTO_FORMAT flag. Defaults to false.
8805 |
8806 |     alsa.noAutoChannels
8807 |     ALSA only. When set to true, disables ALSA's automatic channel conversion by including the
> SND_PCM_NO_AUTO_CHANNELS flag. Defaults to false.
8808 |
8809 |     alsa.noAutoResample
8810 |     ALSA only. When set to true, disables ALSA's automatic resampling by including the
> SND_PCM_NO_AUTO_RESAMPLE flag. Defaults to false.
8811 |
8812 |     pulse.pStreamNamePlayback
8813 |     PulseAudio only. Sets the stream name for playback.
8814 |
8815 |     pulse.pStreamNameCapture
8816 |     PulseAudio only. Sets the stream name for capture.
8817 |
8818 |     pulse.channelMap

```

```

8819 |         PulseAudio only. Sets the channel map that is requested from PulseAudio. See
      > MA_PA_CHANNEL_MAP_* constants. Defaults to MA_PA_CHANNEL_MAP_AIFF.
8820 |
8821 |         coreaudio.allowNominalSampleRateChange
8822 |         Core Audio only. Desktop only. When enabled, allows the sample rate of the device to be
      > changed at the operating system level. This
8823 |         is disabled by default in order to prevent intrusive changes to the user's system. This is
      > useful if you want to use a sample rate
8824 |         that is known to be natively supported by the hardware thereby avoiding the cost of
      > resampling. When set to true, miniaudio will
8825 |         find the closest match between the sample rate requested in the device config and the sample
      > rates natively supported by the
8826 |         hardware. When set to false, the sample rate currently set by the operating system will
      > always be used.
8827 |
8828 |         openssl.streamType
8829 |         OpenSSL only. Explicitly sets the stream type. If left unset
      > ('ma_openssl_stream_type_default'), the
8830 |         stream type will be left unset. Think of this as the type of audio you're playing.
8831 |
8832 |         openssl.recordingPreset
8833 |         OpenSSL only. Explicitly sets the type of recording your program will be doing. When left
8834 |         unset, the recording preset will be left unchanged.
8835 |
8836 |         aaudio.usage
8837 |         AAudio only. Explicitly sets the nature of the audio the program will be consuming. When
8838 |         left unset, the usage will be left unchanged.
8839 |
8840 |         aaudio.contentType
8841 |         AAudio only. Sets the content type. When left unset, the content type will be left
      > unchanged.
8842 |
8843 |         aaudio.inputPreset
8844 |         AAudio only. Explicitly sets the type of recording your program will be doing. When left
8845 |         unset, the input preset will be left unchanged.
8846 |
8847 |         aaudio.noAutoStartAfterReroute
8848 |         AAudio only. Controls whether or not the device should be automatically restarted after a
8849 |         stream reroute. When set to false (default) the device will be restarted automatically;
8850 |         otherwise the device will be stopped.
8851 |
8852 |
8853 | Once initialized, the device's config is immutable. If you need to change the config you will need
      > to initialize a new device.
8854 |
8855 | After initializing the device it will be in a stopped state. To start it, use `ma_device_start()`.
8856 |
8857 | If both `periodSizeInFrames` and `periodSizeInMilliseconds` are set to zero, it will default to
      > `MA_DEFAULT_PERIOD_SIZE_IN_MILLISECONDS_LOW_LATENCY` or
8858 | `MA_DEFAULT_PERIOD_SIZE_IN_MILLISECONDS_CONSERVATIVE`, depending on whether or not
      > `performanceProfile` is set to `ma_performance_profile_low_latency` or
8859 | `ma_performance_profile_conservative`.
8860 |
8861 | If you request exclusive mode and the backend does not support it an error will be returned. For
      > robustness, you may want to first try initializing the device
8862 | in exclusive mode, and then fall back to shared mode if required. Alternatively you can just request
      > shared mode (the default if you leave it unset in the
8863 | config) which is the most reliable option. Some backends do not have a practical way of choosing
      > whether or not the device should be exclusive or not (ALSA,
8864 | for example) in which case it just acts as a hint. Unless you have special requirements you should
      > try avoiding exclusive mode as it's intrusive to the user.
8865 | Starting with Windows 10, miniaudio will use low-latency shared mode where possible which may make
      > exclusive mode unnecessary.
8866 |
8867 | When sending or receiving data to/from a device, miniaudio will internally perform a format
      > conversion to convert between the format specified by the config
8868 | and the format used internally by the backend. If you pass in 0 for the sample format, channel
      > count, sample rate and channel map, data transmission will run
8869 | on an optimized pass-through fast path. You can retrieve the format, channel count and sample rate
      > by inspecting the `playback/capture.format`,
8870 | `playback/capture.channels` and `sampleRate` members of the device object.
8871 |
8872 | When compiling for UWP you must ensure you call this function on the main UI thread because the
      > operating system may need to present the user with a message
8873 | asking for permissions. Please refer to the official documentation for ActivateAudioInterfaceAsync()
      > for more information.
8874 |
8875 | ALSA Specific: When initializing the default device, requesting shared mode will try using the
      > "dmix" device for playback and the "dsnoop" device for capture.

```

```

8876 | If these fail it will try falling back to the "hw" device.
8877 |
8878 |
8879 | Example 1 - Simple Initialization
8880 | -----
8881 | This example shows how to initialize a simple playback device using a standard configuration. If you
> are just needing to do simple playback from the default
8882 | playback device this is usually all you need.
8883 |
8884 | ```c
8885 | ma_device_config config = ma_device_config_init(ma_device_type_playback);
8886 | config.playback.format = ma_format_f32;
8887 | config.playback.channels = 2;
8888 | config.sampleRate = 48000;
8889 | config.dataCallback = ma_data_callback;
8890 | config.pMyUserData = pMyUserData;
8891 |
8892 | ma_device device;
8893 | ma_result result = ma_device_init(NULL, &config, &device);
8894 | if (result != MA_SUCCESS) {
8895 |     // Error
8896 | }
8897 | ```
8898 |
8899 |
8900 | Example 2 - Advanced Initialization
8901 | -----
8902 | This example shows how you might do some more advanced initialization. In this hypothetical example
> we want to control the latency by setting the buffer size
8903 | and period count. We also want to allow the user to be able to choose which device to output from
> which means we need a context so we can perform device
8904 | enumeration.
8905 |
8906 | ```c
8907 | ma_context context;
8908 | ma_result result = ma_context_init(NULL, 0, NULL, &context);
8909 | if (result != MA_SUCCESS) {
8910 |     // Error
8911 | }
8912 |
8913 | ma_device_info* pPlaybackDeviceInfos;
8914 | ma_uint32 playbackDeviceCount;
8915 | result = ma_context_get_devices(&context, &pPlaybackDeviceInfos, &playbackDeviceCount, NULL, NULL);
8916 | if (result != MA_SUCCESS) {
8917 |     // Error
8918 | }
8919 |
8920 | // ... choose a device from pPlaybackDeviceInfos ...
8921 |
8922 | ma_device_config config = ma_device_config_init(ma_device_type_playback);
8923 | config.playback.pDeviceID = pMyChosenDeviceID; // <-- Get this from the `id` member of one
> of the `ma_device_info` objects returned by ma_context_get_devices().
8924 | config.playback.format = ma_format_f32;
8925 | config.playback.channels = 2;
8926 | config.sampleRate = 48000;
8927 | config.dataCallback = ma_data_callback;
8928 | config.pUserData = pMyUserData;
8929 | config.periodSizeInMilliseconds = 10;
8930 | config.periods = 3;
8931 |
8932 | ma_device device;
8933 | result = ma_device_init(&context, &config, &device);
8934 | if (result != MA_SUCCESS) {
8935 |     // Error
8936 | }
8937 | ```
8938 |
8939 |
8940 | See Also
8941 | -----
8942 | ma_device_config_init()

8944 | ma_device_start()
8945 | ma_context_init()
8946 | ma_context_get_devices()
8947 | ma_context_enumerate_devices()
8948 | */
8949 | MA_API ma_result ma_device_init(ma_context* pContext, const ma_device_config* pConfig, ma_device*
> pDevice);

```

```

8950 |
8951 | /*
8952 | Initializes a device without a context, with extra parameters for controlling the configuration of
> the internal self-managed context.
8953 |
8954 | This is the same as `ma_device_init()`, only instead of a context being passed in, the parameters
> from `ma_context_init()` are passed in instead. This function
8955 | allows you to configure the internally created context.
8956 |
8957 |
8958 | Parameters
8959 | -----
8960 | backends (in, optional)
8961 |     A list of backends to try initializing, in priority order. Can be NULL, in which case it uses
> default priority order.
8962 |
8963 | backendCount (in, optional)
8964 |     The number of items in `backend`. Ignored if `backend` is NULL.
8965 |
8966 | pContextConfig (in, optional)
8967 |     The context configuration.
8968 |
8969 | pConfig (in)
8970 |     A pointer to the device configuration. Cannot be null. See remarks for details.
8971 |
8972 | pDevice (out)
8973 |     A pointer to the device object being initialized.
8974 |
8975 |
8976 | Return Value
8977 | -----
8978 | MA_SUCCESS if successful; any other error code otherwise.
8979 |
8980 |
8981 | Thread Safety
8982 | -----
8983 | Unsafe. It is not safe to call this function simultaneously for different devices because some
> backends depend on and mutate global state. The same applies to
8984 | calling this at the same time as `ma_device_uninit()`.
8985 |
8986 |
8987 | Callback Safety
8988 | -----
8989 | Unsafe. It is not safe to call this inside any callback.
8990 |
8991 |
8992 | Remarks
8993 | -----
8994 | You only need to use this function if you want to configure the context differently to its defaults.
> You should never use this function if you want to manage
8995 | your own context.
8996 |
8997 | See the documentation for `ma_context_init()` for information on the different context configuration
> options.
8998 |
8999 |
9000 | See Also
9001 | -----

9004 | ma_device_config_init()
9005 | ma_context_init()
9006 | */
9007 | MA_API ma_result ma_device_init_ex(const ma_backend backends[], ma_uint32 backendCount, const
> ma_context_config* pContextConfig, const ma_device_config* pConfig, ma_device* pDevice);
9008 |
9009 | /*
9010 | Uninitializes a device.
9011 |
9012 | This will explicitly stop the device. You do not need to call `ma_device_stop()` beforehand, but
> it's harmless if you do.
9013 |
9014 |
9015 | Parameters
9016 | -----
9017 | pDevice (in)
9018 |     A pointer to the device to stop.
9019 |
9020 |

```

```

9021 | Return Value
9022 | -----
9023 | Nothing
9024 |
9025 |
9026 | Thread Safety
9027 | -----
9028 | Unsafe. As soon as this API is called the device should be considered undefined.
9029 |
9030 |
9031 | Callback Safety
9032 | -----
9033 | Unsafe. It is not safe to call this inside any callback. Doing this will result in a deadlock.
9034 |

9053 |
9054 |
9055 | /*
9056 | Retrieves information about the device.
9057 |
9058 |
9059 | Parameters
9060 | -----
9061 | pDevice (in)
9062 |     A pointer to the device whose information is being retrieved.
9063 |
9064 | type (in)
9065 |     The device type. This parameter is required for duplex devices. When retrieving device
9066 |     information, you are doing so for an individual playback or capture device.
9067 |
9068 | pDeviceInfo (out)
9069 |     A pointer to the `ma_device_info` that will receive the device information.
9070 |
9071 |
9072 | Return Value
9073 | -----
9074 | MA_SUCCESS if successful; any other error code otherwise.
9075 |
9076 |
9077 | Thread Safety
9078 | -----
9079 | Unsafe. This should be considered unsafe because it may be calling into the backend which may or
9080 | may not be safe.
9081 |
9082 |
9083 | Callback Safety
9084 | -----
9085 | Unsafe. You should avoid calling this in the data callback because it may call into the backend
9086 | which may or may not be safe.
9087 | */
9088 | MA_API ma_result ma_device_get_info(ma_device* pDevice, ma_device_type type, ma_device_info*
> pDeviceInfo);
9089 |
9090 |
9091 | /*
9092 | Retrieves the name of the device.
9093 |
9094 |
9095 | Parameters
9096 | -----
9097 | pDevice (in)
9098 |     A pointer to the device whose information is being retrieved.

```

```

9099 |
9100 | type (in)
9101 |     The device type. This parameter is required for duplex devices. When retrieving device
9102 |     information, you are doing so for an individual playback or capture device.
9103 |
9104 | pName (out)
9105 |     A pointer to the buffer that will receive the name.
9106 |
9107 | nameCap (in)
9108 |     The capacity of the output buffer, including space for the null terminator.
9109 |
9110 | pLengthNotIncludingNullTerminator (out, optional)
9111 |     A pointer to the variable that will receive the length of the name, not including the null
9112 |     terminator.
9113 |
9114 |
9115 | Return Value
9116 | -----
9117 | MA_SUCCESS if successful; any other error code otherwise.
9118 |
9119 |
9120 | Thread Safety
9121 | -----
9122 | Unsafe. This should be considered unsafe because it may be calling into the backend which may or
9123 | may not be safe.
9124 |
9125 |
9126 | Callback Safety
9127 | -----
9128 | Unsafe. You should avoid calling this in the data callback because it may call into the backend
9129 | which may or may not be safe.
9130 |
9131 |
9132 | Remarks
9133 | -----
9134 | If the name does not fully fit into the output buffer, it'll be truncated. You can pass in NULL to
9135 | `pName` if you want to first get the length of the name for the purpose of memory allocation of the
9136 | output buffer. Allocating a buffer of size `MA_MAX_DEVICE_NAME_LENGTH + 1` should be enough for
9137 | most cases and will avoid the need for the inefficiency of calling this function twice.
9138 |
9139 | This is implemented in terms of `ma_device_get_info()`.
9140 | */
9141 | MA_API ma_result ma_device_get_name(ma_device* pDevice, ma_device_type type, char* pName, size_t
> nameCap, size_t* pLengthNotIncludingNullTerminator);
9142 |
9143 |
9144 | /*
9145 | Starts the device. For playback devices this begins playback. For capture devices it begins
> recording.
9146 |
9147 | Use `ma_device_stop()` to stop the device.
9148 |
9149 |
9150 | Parameters
9151 | -----
9152 | pDevice (in)
9153 |     A pointer to the device to start.
9154 |
9155 |
9156 | Return Value
9157 | -----
9158 | MA_SUCCESS if successful; any other error code otherwise.
9159 |
9160 |
9161 | Thread Safety
9162 | -----
9163 | Safe. It's safe to call this from any thread with the exception of the callback thread.
9164 |
9165 |
9166 | Callback Safety
9167 | -----
9168 | Unsafe. It is not safe to call this inside any callback.
9169 |
9170 |
9171 | Remarks
9172 | -----
9173 | For a playback device, this will retrieve an initial chunk of audio data from the client before
> returning. The reason for this is to ensure there is valid
9174 | audio data in the buffer, which needs to be done before the device begins playback.

```

```
9175 |
9176 | This API waits until the backend device has been started for real by the worker thread. It also
9177 | > waits on a mutex for thread-safety.
9178 |
9179 | Do not call this in any callback.
9180 |
9181 | See Also
9182 | -----
9183 | ma_device_stop()
9184 | */
9185 | MA_API ma_result ma_device_start(ma_device* pDevice);
9186 |
9187 | /*
9188 | Stops the device. For playback devices this stops playback. For capture devices it stops recording.
9189 |
9190 | Use `ma_device_start()` to start the device again.
9191 |
9192 |
9193 | Parameters
9194 | -----
9195 | pDevice (in)
9196 |     A pointer to the device to stop.
9197 |
9198 |
9199 | Return Value
9200 | -----
9201 | MA_SUCCESS if successful; any other error code otherwise.
9202 |
9203 |
9204 | Thread Safety
9205 | -----
9206 | Safe. It's safe to call this from any thread with the exception of the callback thread.
9207 |
9208 |
9209 | Callback Safety
9210 | -----
9211 | Unsafe. It is not safe to call this inside any callback. Doing this will result in a deadlock.
9212 |
9213 |
9214 | Remarks
9215 | -----
9216 | This API needs to wait on the worker thread to stop the backend device properly before returning. It
9217 | > also waits on a mutex for thread-safety. In addition, some
9218 | backends need to wait for the device to finish playback/recording of the current fragment which can
9219 | > take some time (usually proportionate to the buffer size
9220 | that was specified at initialization time).
9221 |
9222 | Backends are required to either pause the stream in-place or drain the buffer if pausing is not
9223 | > possible. The reason for this is that stopping the device and
9224 | the resuming it with ma_device_start() (which you might do when your program loses focus) may result
9225 | > in a situation where those samples are never output to the
9226 | speakers or received from the microphone which can in turn result in de-syncs.
9227 |
9228 | Do not call this in any callback.
9229 |
9230 | See Also
9231 | -----
9232 | ma_device_start()

9234 | MA_API ma_result ma_device_stop(ma_device* pDevice);
9235 |
9236 | /*
9237 | Determines whether or not the device is started.
9238 |
9239 |
9240 | Parameters
9241 | -----
9242 | pDevice (in)
9243 |     A pointer to the device whose start state is being retrieved.
9244 |
9245 |
9246 | Return Value
9247 | -----
9248 | True if the device is started, false otherwise.
9249 |
9250 |
9251 | Thread Safety
```

```

9249 | -----
9250 | Safe. If another thread calls `ma_device_start()` or `ma_device_stop()` at this same time as this
> function is called, there's a very small chance the return
9251 | value will be out of sync.
9252 |
9253 |
9254 | Callback Safety
9255 | -----
9256 | Safe. This is implemented as a simple accessor.
9257 |
9258 |
9259 | See Also
9260 | -----
9261 | ma_device_start()
9262 | ma_device_stop()
9263 | */
9264 | MA_API ma_bool32 ma_device_is_started(const ma_device* pDevice);
9265 |
9266 |
9267 | /*
9268 | Retrieves the state of the device.
9269 |
9270 |
9271 | Parameters
9272 | -----
9273 | pDevice (in)
9274 |     A pointer to the device whose state is being retrieved.
9275 |
9276 |
9277 | Return Value
9278 | -----
9279 | The current state of the device. The return value will be one of the following:
9280 |
9281 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9282 | | ma_device_state_uninitialized | Will only be returned if the device is in the middle of
> initialization. |
9283 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9284 | | ma_device_state_stopped      | The device is stopped. The initial state of the device after
> initialization. |
9285 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9286 | | ma_device_state_started      | The device started and requesting and/or delivering audio
> data. |
9287 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9288 | | ma_device_state_starting     | The device is in the process of starting.
> |
9289 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9290 | | ma_device_state_stopping     | The device is in the process of stopping.
> |
9291 | +-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
> +-----+
9292 |
9293 |
9294 | Thread Safety
9295 | -----
9296 | Safe. This is implemented as a simple accessor. Note that if the device is started or stopped at the
> same time as this function is called,
9297 | there's a possibility the return value could be out of sync. See remarks.
9298 |
9299 |
9300 | Callback Safety
9301 | -----
9302 | Safe. This is implemented as a simple accessor.
9303 |
9304 |
9305 | Remarks
9306 | -----
9307 | The general flow of a devices state goes like this:
9308 |
9309 | ```
9310 | ma_device_init() -> ma_device_state_uninitialized -> ma_device_state_stopped
9311 | ma_device_start() -> ma_device_state_starting      -> ma_device_state_started
9312 | ma_device_stop() -> ma_device_state_stopping      -> ma_device_state_stopped
9313 | ```
9314 |

```

```

9315 | When the state of the device is changed with `ma_device_start()` or `ma_device_stop()` at this same
> time as this function is called, the
9316 | value returned by this function could potentially be out of sync. If this is significant to your
> program you need to implement your own
9317 | synchronization.
9318 | */
9319 | MA_API ma_device_state ma_device_get_state(const ma_device* pDevice);
9320 |
9321 |
9322 | /*
9323 | Performs post backend initialization routines for setting up internal data conversion.
9324 |
9325 | This should be called whenever the backend is initialized. The only time this should be called from
9326 | outside of miniaudio is if you're implementing a custom backend, and you would only do it if you
9327 | are reinitializing the backend due to rerouting or reinitializing for some reason.
9328 |
9329 | Parameters
9330 | -----
9331 | pDevice [in]
9332 |     A pointer to the device.
9333 |
9334 | deviceType [in]
9335 |     The type of the device that was just reinitialized.
9336 |
9337 | pPlaybackDescriptor [in]
9338 |     The descriptor of the playback device containing the internal data format and buffer sizes.
9339 |
9340 | pCaptureDescriptor [in]
9341 |     The descriptor of the capture device containing the internal data format and buffer sizes.
9342 |
9343 | Return Value
9344 | -----
9345 | MA_SUCCESS if successful; any other error otherwise.
9346 |
9347 | Thread Safety
9348 | -----
9349 | Unsafe. This will be reinitializing internal data converters which may be in use by another thread.
9350 |
9351 | Callback Safety
9352 | -----
9353 | Unsafe. This will be reinitializing internal data converters which may be in use by the callback.
9354 |
9355 | Remarks
9356 | -----
9357 | For a duplex device, you can call this for only one side of the system. This is why the deviceType
9358 | is specified as a parameter rather than deriving it from the device.
9359 |
9360 | You do not need to call this manually unless you are doing a custom backend, in which case you need
9361 | only do it if you're manually performing rerouting or reinitialization.
9362 | */
9363 | MA_API ma_result ma_device_post_init(ma_device* pDevice, ma_device_type deviceType, const
> ma_device_descriptor* pPlaybackDescriptor, const ma_device_descriptor* pCaptureDescriptor);
9364 |
9365 |
9366 | /*
9367 | Sets the master volume factor for the device.
9368 |
9369 | The volume factor must be between 0 (silence) and 1 (full volume). Use
> `ma_device_set_master_volume_db()` to use decibel notation, where 0 is full volume and
9370 | values less than 0 decreases the volume.
9371 |
9372 | Parameters
9373 | -----
9374 | pDevice (in)
9375 |     A pointer to the device whose volume is being set.
9376 |
9377 | volume (in)
9378 |     The new volume factor. Must be >= 0.
9379 |
9380 | Return Value
9381 | -----
9382 | MA_SUCCESS if the volume was set successfully.

```

```

9390 | MA_INVALID_ARGS if pDevice is NULL.
9391 | MA_INVALID_ARGS if volume is negative.
9392 |
9393 |
9394 | Thread Safety
9395 | -----
9396 | Safe. This just sets a local member of the device object.
9397 |
9398 |
9399 | Callback Safety
9400 | -----
9401 | Safe. If you set the volume in the data callback, that data written to the output buffer will have
> the new volume applied.
9402 |
9403 |
9404 | Remarks
9405 | -----
9406 | This applies the volume factor across all channels.
9407 |
9408 | This does not change the operating system's volume. It only affects the volume for the given
> `ma_device` object's audio stream.

9554 | Called from the data callback of asynchronous backends to allow miniaudio to process the data and
> fire the miniaudio data callback.
9555 |
9556 |
9557 | Parameters
9558 | -----
9559 | pDevice (in)
9560 |     A pointer to device whose processing the data callback.
9561 |
9562 | pOutput (out)
9563 |     A pointer to the buffer that will receive the output PCM frame data. On a playback device this
> must not be NULL. On a duplex device
9564 |     this can be NULL, in which case pInput must not be NULL.
9565 |
9566 | pInput (in)
9567 |     A pointer to the buffer containing input PCM frame data. On a capture device this must not be
> NULL. On a duplex device this can be
9568 |     NULL, in which case `pOutput` must not be NULL.
9569 |
9570 | frameCount (in)
9571 |     The number of frames being processed.
9572 |
9573 |
9574 | Return Value
9575 | -----
9576 | MA_SUCCESS if successful; any other result code otherwise.
9577 |
9578 |
9579 | Thread Safety
9580 | -----
9581 | This function should only ever be called from the internal data callback of the backend. It is safe
> to call this simultaneously between a
9582 | playback and capture device in duplex setups.
9583 |
9584 |
9585 | Callback Safety
9586 | -----
9587 | Do not call this from the miniaudio data callback. It should only ever be called from the internal
> data callback of the backend.
9588 |
9589 |
9590 | Remarks
9591 | -----
9592 | If both `pOutput` and `pInput` are NULL, and error will be returned. In duplex scenarios, both
> `pOutput` and `pInput` can be non-NULL, in
9593 | which case `pInput` will be processed first, followed by `pOutput`.
9594 |
9595 | If you are implementing a custom backend, and that backend uses a callback for data delivery, you'll
> need to call this from inside that
9596 | callback.
9597 | */
9598 | MA_API ma_result ma_device_handle_backend_data_callback(ma_device* pDevice, void* pOutput, const
> void* pInput, ma_uint32 frameCount);
9599 |
9600 |
9601 | /*
9602 | Calculates an appropriate buffer size from a descriptor, native sample rate and performance profile.
9603 |
9604 | This function is used by backends for helping determine an appropriately sized buffer to use with
9605 | the device depending on the values of `periodSizeInFrames` and `periodSizeInMilliseconds` in the
9606 | `pDescriptor` object. Since buffer size calculations based on time depends on the sample rate, a
9607 | best guess at the device's native sample rate is also required which is where `nativeSampleRate`
9608 | comes in. In addition, the performance profile is also needed for cases where both the period size
9609 | in frames and milliseconds are both zero.
9610 |
9611 |

```

```

9612 | Parameters
9613 | -----
9614 | pDescriptor (in)
9615 |     A pointer to device descriptor whose `periodSizeInFrames` and `periodSizeInMilliseconds` members
9616 |     will be used for the calculation of the buffer size.
9617 |
9618 | nativeSampleRate (in)
9619 |     The device's native sample rate. This is only ever used when the `periodSizeInFrames` member of
9620 |     `pDescriptor` is zero. In this case, `periodSizeInMilliseconds` will be used instead, in which
9621 |     case a sample rate is required to convert to a size in frames.
9622 |
9623 | performanceProfile (in)
9624 |     When both the `periodSizeInFrames` and `periodSizeInMilliseconds` members of `pDescriptor` are
9625 |     zero, miniaudio will fall back to a buffer size based on the performance profile. The profile
9626 |     to use for this calculation is determine by this parameter.
9627 |
9628 |
9629 | Return Value
9630 | -----
9631 | The calculated buffer size in frames.
9632 |
9633 |
9634 | Thread Safety
9635 | -----
9636 | This is safe so long as nothing modifies `pDescriptor` at the same time. However, this function
9637 | should only ever be called from within the backend's device initialization routine and therefore
9638 | shouldn't have any multithreading concerns.
9639 |
9640 |
9641 | Callback Safety
9642 | -----
9643 | This is safe to call within the data callback, but there is no reason to ever do this.
9644 |
9645 |
9646 | Remarks
9647 | -----
9648 | If `nativeSampleRate` is zero, this function will fall back to `pDescriptor->sampleRate`. If that
9649 | is also zero, `MA_DEFAULT_SAMPLE_RATE` will be used instead.
9650 | */
9651 | MA_API ma_uint32 ma_calculate_buffer_size_in_frames_from_descriptor(const ma_device_descriptor*
> pDescriptor, ma_uint32 nativeSampleRate, ma_performance_profile performanceProfile);

9669 |
9670 | /*
9671 | Retrieves compile-time enabled backends.
9672 |
9673 |
9674 | Parameters
9675 | -----
9676 | pBackends (out, optional)
9677 |     A pointer to the buffer that will receive the enabled backends. Set to NULL to retrieve the
> backend count. Setting
9678 |     the capacity of the buffer to `MA_BACKEND_COUNT` will guarantee it's large enough for all
> backends.
9679 |
9680 | backendCap (in)
9681 |     The capacity of the `pBackends` buffer.
9682 |
9683 | pBackendCount (out)
9684 |     A pointer to the variable that will receive the enabled backend count.
9685 |
9686 |
9687 | Return Value

```

```

9688 | -----
9689 | MA_SUCCESS if successful.
9690 | MA_INVALID_ARGS if `pBackendCount` is NULL.
9691 | MA_NO_SPACE if the capacity of `pBackends` is not large enough.
9692 |
9693 | If `MA_NO_SPACE` is returned, the `pBackends` buffer will be filled with `*pBackendCount` values.
9694 |
9695 |
9696 | Thread Safety
9697 | -----
9698 | Safe.
9699 |
9700 |
9701 | Callback Safety
9702 | -----
9703 | Safe.
9704 |
9705 |
9706 | Remarks
9707 | -----
9708 | If you want to retrieve the number of backends so you can determine the capacity of `pBackends`
9709 | > buffer, you can call
9710 | this function with `pBackends` set to NULL.
9711 | This will also enumerate the null backend. If you don't want to include this you need to check for
9712 | > `ma_backend_null`
9713 | when you enumerate over the returned backends and handle it appropriately. Alternatively, you can
9714 | > disable it at
9715 | compile time with `MA_NO_NULL`.
9716 |
9717 | The returned backends are determined based on compile time settings, not the platform it's currently
9718 | > running on. For
9719 | example, PulseAudio will be returned if it was enabled at compile time, even when the user doesn't
9720 | > actually have
9721 | PulseAudio installed.
9722 |
9723 | Example 1
9724 | -----
9725 | The example below retrieves the enabled backend count using a fixed sized buffer allocated on the
9726 | > stack. The buffer is
9727 | given a capacity of `MA_BACKEND_COUNT` which will guarantee it'll be large enough to store all
9728 | > available backends.
9729 | Since `MA_BACKEND_COUNT` is always a relatively small value, this should be suitable for most
9730 | > scenarios.
9731 |
9732 | ```
9733 | ma_backend enabledBackends[MA_BACKEND_COUNT];
9734 | size_t enabledBackendCount;
9735 |
9736 | result = ma_get_enabled_backends(enabledBackends, MA_BACKEND_COUNT, &enabledBackendCount);
9737 | if (result != MA_SUCCESS) {
9738 |     // Failed to retrieve enabled backends. Should never happen in this example since all inputs are
9739 |     > valid.
9740 | }
9741 | ```
